## **Chapter 1 Executive Summary**

This report documents the condition of highway pavements under the jurisdiction of the Minnesota Department of Transportation (Mn/DOT). The data presented herein is in a different form than similar data presented in a document titled "2004 Pavement Condition Executive Summary." The data in the Executive Summary report compares current pavement condition data with Mn/DOT's statewide pavement performance measures. The data in this report is presented using weighted averages for both current and historical conditions. Each type of reporting technique provides certain insight into the pavement performance trends of the trunk highway system. The Executive Summary report listed above can be obtained by contacting the Pavement Management Engineer at the address listed at the top of page 3.

Pavement condition ratings in this report are based on routine surveys conducted in 2004 for pavement smoothness and surface distress (cracking, patching, etc.). Numerical indices are calculated for both smoothness and distress based on these surveys. In addition, a composite index of these two measurements, called the Pavement Quality Index (PQI), is used to represent the overall condition of the pavement. The PQI ranges from 0.0 to 4.5 and is divided into five equal parts and given a descriptive name, either "Very Good," "Good," "Fair," "Poor," or "Very Poor." Figure 1-1 shows the distribution of the current PQI values of Minnesota's highways.

Figure 1-1 Statewide Pavement Quality Index (PQI) Distribution

The PQI of each segment of pavement can be used to compare current and past conditions. From this comparison, trends can be developed and predictions of future condition can be made. Figure 1-2 shows the average PQI for the trunk highway system in Minnesota from 1995 to 2004. It is apparent from this figure that there has been a steady decline in the condition of Mn/DOT's highway pavements, as measured by the average PQI, since 2001. An overview of Mn/DOT's highway system is provided in Chapter 2.

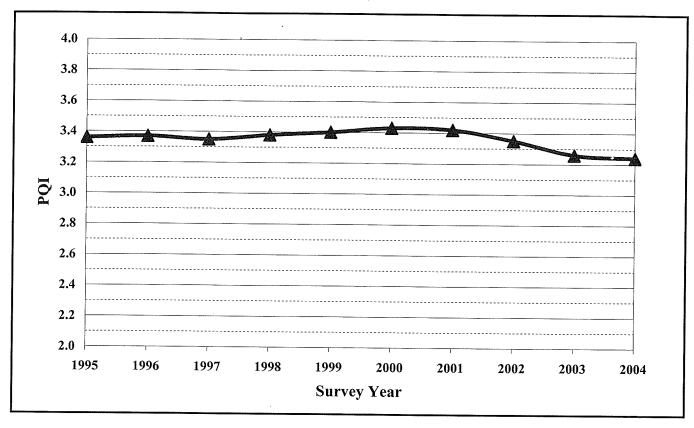

Figure 1-2 Statewide Pavement Quality Index (PQI), 1995-2004

As mentioned previously, the PQI is derived from two other measures of pavement condition: smoothness and surface distress. Although it is useful to have one composite number like the PQI to characterize condition, the two indices from which it is derived may provide greater insight into the rate and mechanisms of deterioration, as well as the effectiveness and cost of maintenance and rehabilitation.

The Present Serviceability Rating (PSR) measures the pavement smoothness. The Surface Rating (SR) indirectly measures the condition of the pavement structure based upon surface distress. The procedures and techniques by which the PQI, SR, and PSR are developed can be found in the "Mn/DOT Surface Distress Manual" and the "Pavement Condition Rating Overview" available from the Pavement Management Unit website: <a href="https://www.mrr.dot.state.mn.us/pavement/pvmtmgmt/pavemgmt.asp">www.mrr.dot.state.mn.us/pavement/pvmtmgmt/pavemgmt.asp</a>.

The remainder of this report, specifically Chapters 4 through 6, presents more detailed data of the current and historical values of the three performance indices (PSR, SR, and PQI). The information is further refined to allow for comparison between different functional classes or route types, as well as between districts.

The current and historical values of the PQI, SR, and PSR, together with the distress and ride measurements from which they are calculated, are maintained in a computer database. The Pavement Management Unit in the Office of Materials maintains a computer application called Highway Pavement Management Application (HPMA). HPMA can be used to develop a wide variety of statistical information about very detailed subsets of highway pavements and to prioritize pavement segments based upon the cost-effectiveness of applicable maintenance and rehabilitation techniques. Requests to perform a specific analysis or for assistance in running HPMA should be directed to David Janisch, Pavement Management Engineer, at 651-779-5567 or <a href="maintaineq">dave.janisch@dot.state.mn.us</a>.

#### **General Observations**

Some general observations that can be made regarding the data in this report are:

- The condition of the Minnesota trunk highway system, as measured by the average PQI, decreased slightly in 2004. Since the average PSR remained virtually the same as last year, the decrease in PQI is attributed to a decrease in the average SR. A drop in the SR indicates there were more cracks and/or higher severity cracks on Mn/DOT highways in 2004.
  - o The average PQI of the entire trunk highway system decreased slightly in 2004, the fourth straight year of decline. This is attributed to a matching decline of the average SR.
  - o The average PSR of the trunk highway system remained virtually the same as 2003.
  - o The average SR of the trunk highway system decreased slightly in 2004, the fourth straight year of decline.
- While the smoothness of the entire trunk highway system, as characterized by the average PSR, remained virtually unchanged in 2004, the smoothness of the interstate system decreased for the fourth straight year and is now below that of the non-interstate system. This is only the second time this has occurred (1992) since Mn/DOT has been measuring pavement condition.
- District 7 was the only district to show an increase in each of the three pavement condition indices in 2004 (PQI, PSR, and SR).

#### **Endnotes for Chapter 1**

The pavement conditions of bridges, ramps, loops, and a portion of TH 74 that has a gravel surface are not included in this report.

This page intentionally left blank.

## Chapter 2 Minnesota's Trunk Highway System

Minnesota's trunk highway system consists of approximately 11,900 centerline miles of pavement. Slightly less than 9,500 miles are two-lane undivided routes; the remaining 2,400 miles are multilane divided routes such as interstate routes.

In the pavement management system, roadway miles are also used to quantify the trunk highway system. A roadway mile is equal to one mile of undivided highway or one mile of divided highway, in one direction only. For example, one mile of I-94 counts as two roadway miles because the eastbound and westbound directions are counted as separate lengths of roadway. This is done to account for instances in which—due to differences in construction or design—one direction of a divided road is different from another. There currently are 14,297 roadway miles of trunk highway with pavement condition ratings. The pavement condition on some of the longer bridges in the state is not measured.

#### Mn/DOT Districts

The direct management of Minnesota's trunk highway system is the responsibility of eight districts. The district staff prioritizes highway segments for routine maintenance, preventive maintenance, rehabilitation, and reconstruction work. The types of work performed are determined by the district staff with the concurrence of Central Office staff. The boundaries of each of the eight districts are shown in Figure 2-1. Throughout this report, the data is analyzed on a district basis.

The established district boundaries somewhat complicate the implementation of transportation improvements because they do not follow county boundaries. For the planning and implementation of transportation improvements, Mn/DOT seeks input from county and municipal officials and staff. As a result, it is helpful for local officials to have only one Mn/DOT liaison and vice versa. Area Transportation Partnership (ATP) is the term for districts with boundaries that have been modified to follow county boundaries. Figure 2-2 is a map of the ATP boundaries.

#### **Route Types**

Three route types—Interstate, U.S., and Minnesota routes—comprise the trunk highway system that is under the jurisdiction of Mn/DOT. Figure 2-3 is a pie chart showing the percentage of mileage for each of the three route types. The trunk highway system may also be characterized in a number of other ways such as by pavement type or design standards.

Figure 2-1 District Boundaries

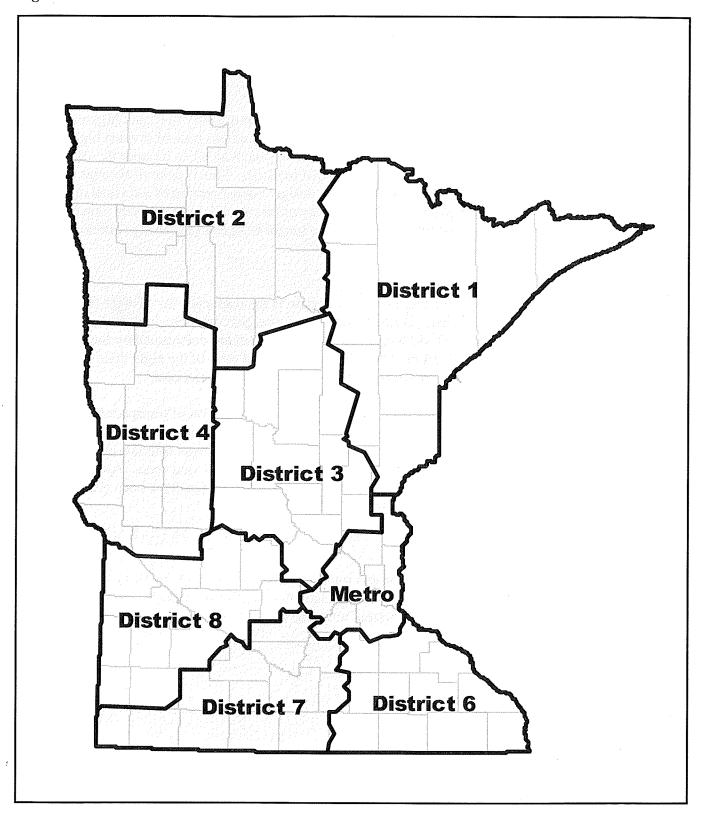

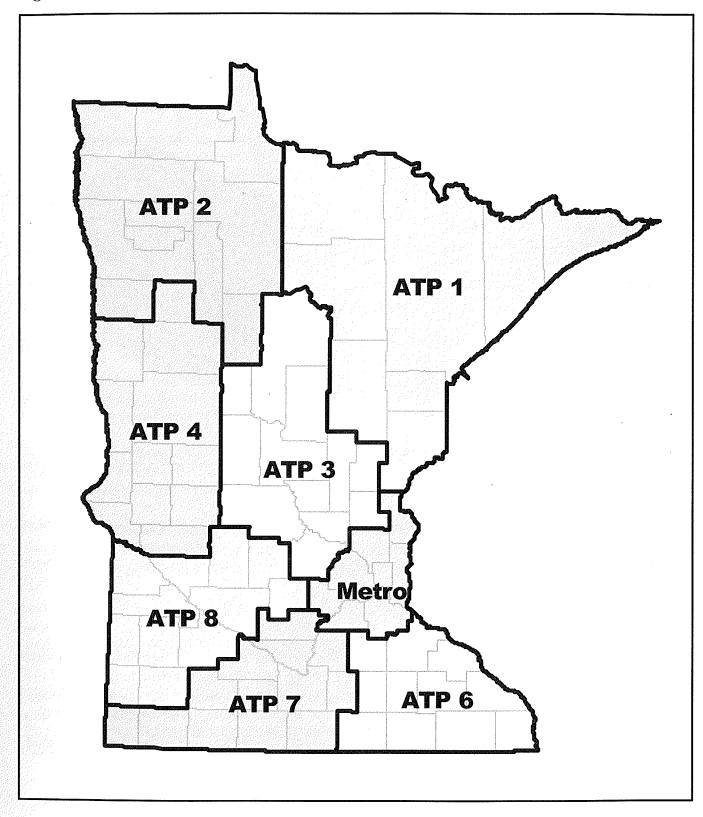

Figure 2-2 Area Transportation Partnership Boundaries

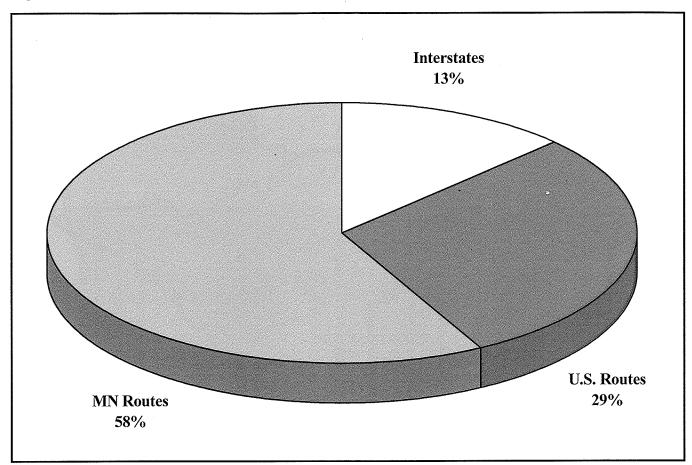

Figure 2-3 Statewide Highway Route Type Distribution (Roadway Miles)

#### Pavement Types

In the pavement management system, there are seven different pavement types. Assigning each pavement section one of these pavement types allows for better head-to-head comparison and more accurate prediction of future condition and expected performance. The seven pavement types are defined as follows.

#### Bituminous—Aggregate Base (BAB)

Bituminous pavements, which are commonly called asphalt, are utilized for both new construction and as an overlay for rehabilitation of an existing pavement. When used for new construction, layers of bituminous may be placed upon layers of aggregate base, which have controlled aggregate gradations. This is termed Bituminous Aggregate Base and abbreviated BAB. Cold in-place recycling (CIR) and full depth reclamation of existing bituminous pavements are also classified as BAB.

#### Bituminous—Full Depth (BFD)

With sufficiently increased thickness of the bituminous layers, the aggregate base may be eliminated. Such pavement is termed Bituminous-Full Depth and abbreviated BFD. Although Full Depth Bituminous was used extensively in the 1970s and 1980s, its use by Mn/DOT has been discontinued because of long-term performance concerns.

#### Bituminous Over Bituminous (BOB) & Bituminous Over Concrete (BOC)

Bituminous that is used as an overlay on top of existing bituminous surfaces is termed Bituminous Over Bituminous or BOB, while bituminous used as an overlay on concrete pavement is abbreviated BOC. Overlays are primarily used to minimize road roughness and/or increase pavement structural capacity.

#### Concrete—Doweled (CD)

For new Portland Cement Concrete pavement construction, Mn/DOT currently uses only concrete with dowel bars (i.e., steel rods) connecting adjacent panels. Dowel bars transfer vehicle loads from one slab to another, substantially reducing faulting that can occur at the joints. Unbonded concrete overlays, which are used extensively by Mn/DOT on top of deteriorated concrete, are also classified as concrete doweled pavements.

#### Concrete—Undoweled (CU)

Concrete pavement without dowels between the panels is abbreviated CU. Pavements of this type are no longer built because the differential movement between panels causes roughness.

#### Continuously Reinforced Concrete Pavement (CRCP)

Concrete continuously formed without panel joints but with continuous steel reinforcement is referred to as Continuously Reinforced Concrete Pavement or CRCP. CRCP is no longer used in Minnesota because of past performance problems related to corrosion of the steel caused by de-icing salt.

Table 2-1 shows a breakdown by the different pavement types for each district and for the entire state. Bituminous pavements (BAB, BFD, BOB, and BOC) account for nearly eighty-five percent of the total mileage. Doweled concrete comprises roughly fourteen percent of the total mileage.

Table 2-1 Roadway Miles of Pavement for State & Districtsii

Pavement	State	D-1	D-2	D-3	D-4	D-6	D-7	D-8	Metro
BAB	968	217	133	235	99	80	34	47	122
BFD	156	23	3	19	4	38	4	26	39
BOB	7,836	1,180	1,439	1,317	1,050	786	620	856	588
BOC	3,165	205	292	190	481	526	578	344	548
CD	2,029	234	71	194 ,	161	385	377	150	457
CU	126	6	13	27	19	4	24	32	0
CRCP	18	0	0	0	18	0	0	0	0
Total	14,297	1,866	1,952	1,982	1,832	1,819	1,638	1,455	1,755

#### **Functional Class**

The safe and expedient movement of traffic conflicts with the other major goal of highway design: providing access to residences, businesses, and recreational areas. Accordingly, highways are grouped into different functional classes, which provide different combinations of mobility and access such that the integrated highway system achieves both of these goals. The design and functional class vary based upon whether the highway serves a rural or urban area. The use of the highway can be further subdivided into one of four broad classes: interstate, principal arterial, minor arterial, and collector/local. Figure 2-4 shows the percentage of roadway mileage for these functional class groups.

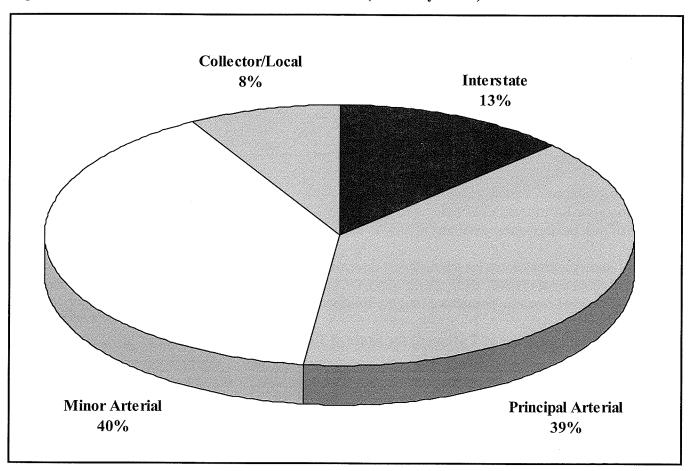

Figure 2-4 Statewide Functional Class Distribution (Roadway Miles)

The interstate system connects every large community in the United States with controlled access, high design speed freeways. The Federal Aid Highway acts of 1944 and 1956 created the interstate system, formally the "National System of Interstate and Defense Highways." The interstate system has become such a critical part of our transportation system that Chapter 5 is devoted exclusively to its condition.

Limited access and a capacity to move relatively large volumes of traffic in an expedient manner characterize arterial highways. In rural areas, arterials provide a system of integrated continuous connections to the major urban areas at a level of service suitable for statewide travel. In urban areas, arterials are high traffic volume roadways that serve the major centers of activity within the urban area. Arterials are subdivided into principal and minor categories. This further distinction is based upon the relative distribution of providing access and mobility, the relative importance of the areas they serve, their length, and traffic volumes.

Collector routes are characterized by roughly even distribution of access and mobility with generally lower traffic volumes than arterials. In rural areas, collectors primarily serve as connections to the arterial system and provide for travel within a county. In urban areas, collectors act as an intermediate connection between the arterial system and the points of origin and destination. Urban collectors typically serve commercial and industrial areas.

Their many points of direct access to the surrounding area characterize local roads. Speeds and traffic volumes are lower and trip distances are shorter. Local highways connect to higher priority collectors or arterials to provide mobility over greater distances.

#### **Pavement Rehabilitation**

The effects of repeated heavy loads and weather extremes on pavement condition necessitate an ongoing program of maintenance and rehabilitation. Rehabilitation and reconstruction are activities that upgrade the pavement structure of a highway after the cumulative loads exceed its actual capacity or the pavement has deteriorated for other reasons. Rehabilitation work is frequently undertaken with safety enhancements, intersection upgrades, or bridgework. Rehabilitation projects for bituminous pavements primarily include overlays, with or without milling. Rehabilitation projects for concrete pavements include major joint repairs and bituminous or unbonded concrete overlays. Figure 2-5 shows the average number of years between original construction and first rehabilitation for pavements built since 1955. Statewide, the average age when the first rehabilitation for bituminous and concrete pavements is performed is 16 and 19 years, respectively. For bituminous, the first rehabilitation is considered to be when an overlay is placed or the road is reconstructed. For concrete, the first rehabilitation is considered to be when the pavement is overlaid, reconstructed, or has a major joint repair project.

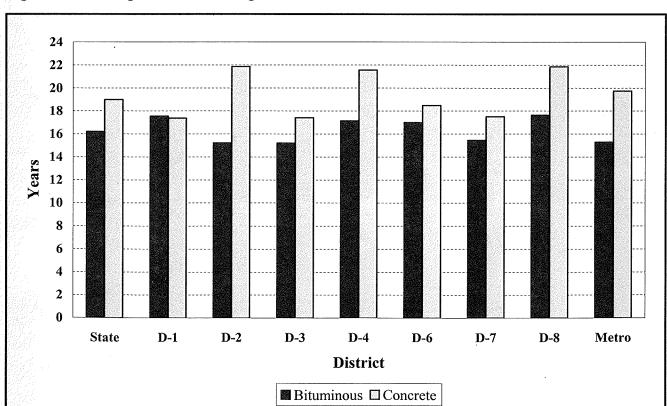

Figure 2-5 Average Time from Original Construction to First Rehabilitation/Reconstruction

#### **Preventive Maintenance**

Mn/DOT has endorsed the concept of using pavement preventive maintenance (PPM) on pavements in good structural condition as a way to cost-effectively extend usable service life. In 2001, a goal of \$40 million dollars per year was set for preventive maintenance projects. Approximately one-third of the trunk highway system has been identified as potentially benefiting from preventive maintenance.

Microsurfacing, crack sealing, crack repair, rut filling, chip sealing, and thin hot mix overlays are examples of bituminous pavement preventive maintenance activities. Joint resealing, diamond grinding, and minor Concrete Pavement Repair (which includes relatively small quantities of repair of spalled joints, cracked corners, and delaminated areas) are concrete pavement preventive maintenance activities.

Beginning in 2008, changes to this process will be made as a result of the completion of the district long range plans. The 20-year district plans demonstrated that \$40M is not necessarily the optimal amount of annual PPM spending needed to meet the established pavement performance measures of smoothness and remaining service life. Using the pavement management system, the optimal amount of PPM spending needed to meet the pavement performance measures can be determined. This amount will change each year depending on the condition of the system compared to the performance targets.

#### **Endnotes for Chapter 2**

Distances for undivided highways are given in miles measured along the centerline of the highway, irrespective of the number of lanes. Divided highways are treated as separate roadways in each direction for the computation of distance. Due to rounding, tabular data entries do not necessarily sum to the totals displayed.

There is also a portion of TH 74 in D-6, about 9 miles long, in the Whitewater Wildlife Area, with a gravel surface. This is the only gravel surfaced trunk highway in Minnesota.

## **Chapter 3 Pavement Condition Measurements**

The process of measuring the condition of Minnesota's trunk highway system begins with maintaining a database of a large number of attributes for each highway. The attributes include data on length, lane width, shoulder width and type, pavement type and thickness, dates of original construction and rehabilitation, traffic counts, and much more. This information is stored on Mn/DOT's Transportation Information System (TIS) as well as the pavement management software, HPMA. Currently, the primary link between the information stored on TIS and the events and conditions on the actual highway is a sequence of reference posts along each highway at approximately one-mile spacing.

Pavement condition data is normally reported in one of two formats. The first is on a mile-by-mile basis, between consecutive reference posts and anywhere the pavement type changes. The advantage of reporting the data in this format is that it provides the finest level of detail on the condition of the highway system. The second format is by longer project or design segments. These segments typically coincide with paving projects and tend to represent longer sections of uniform pavement. For these sections, a length-weighted condition is reported based on the mile-by-mile results. The longer sections allow for better project identification and selection.

Mn/DOT determines the pavement condition using a specially equipped Video Inspection Vehicle (VIV), manufactured by Pathways Services, Inc.

The VIV measures the longitudinal profile of the roadway in addition to capturing video images of the pavement surface and digital images of the surrounding area. In addition, transverse oriented distress such as rutting and faulting are measured.

Mn/DOT's two primary measures of pavement condition are surface distress (cracks, ruts, etc.) and pavement roughness.

#### **Pavement Surface Distress**

Generally, pavement distress measurements are made over the first 500 feet of every mile, beginning at each reference post or change in pavement type. The pavement surface is filmed with two downward-looking cameras mounted on the VIV. Trained technicians at the Office of Materials view the images and determine the type, severity, and amount of the various pavement distresses using special computer workstations. This procedure provides consistent measurement of surface distresses for all trunk highway pavements throughout the state, as well as a permanent record of conditions at the time of rating. An index called the Surface Rating (SR) is calculated from the distress information. The SR is intended to correspond to a rating by a panel of experienced pavement engineers. SR values range from 0.0 to 4.0. An SR of 4.0 corresponds to a new pavement with no surface distresses. An extremely distressed pavement will have an SR below 2.0.

The VIV is also equipped with lasers mounted across the front of the vehicle. The lasers measure the distance from the van's reference bar to the pavement surface. Rutting and faulting are types of surface distress measured with the lasers. By comparing the value of the lasers mounted across the front of the VIV, an estimate of the transverse profile can be made. Rut depths exceeding 0.5 inches are classified as a surface distress because they allow water to pond in the rut, resulting in icing or hydroplaning. Excessive rut depths also indicate a lack of required structural strength for the loads to which the pavement is subjected. On concrete pavements, faulting over 0.25 inches is considered large enough to warrant attention. If either of these thresholds is exceeded, the SR is reduced.

#### **Pavement Roughness**

As the VIV travels down the highway, the lasers are continuously firing. This data is used to determine the longitudinal profile of the roadway. If the roadway were perfectly smooth, the measurements would always be the same as the vehicle traveled along it. However, as bumps and dips are encountered the distance to the pavement surface changes. These deviations from a perfectly smooth road are defined as pavement roughness. The road surface profile is continuously measured over the mile-by-mile sections. For each section, an internationally based parameter termed the International Roughness Index (IRI) is calculated. The IRI is typically reported in meters/kilometer or inches/mile. It is based on the total vertical departure from a perfectly smooth profile that a standard vehicle would experience if it were driven over the section of roadway. To correlate the IRI measured by the VIV to how it is perceived or tolerated by drivers, Mn/DOT periodically assembles groups of people to rank pavement roughness on a scale of 0.0 to 5.0. An equation is then developed to compute the Present Serviceability Rating (PSR) from the IRI values. A PSR value of 5.0 would correspond to a perfectly smooth pavement surface. New pavements typically have a PSR of about 4.3. Most people feel a pavement is uncomfortable to drive on for long distances once the PSR reaches 2.5. For pavement design purposes, this is also considered to be the end of the pavement's design life.

The Pavement Quality Index (PQI) is a composite index derived from SR and PSR values to give an overall rating to each pavement segment. The PQI value is the geometric mean of the SR and PSR values (the square root of the product of the SR and PSR). The PQI ranges from 0.0 to 4.5.

The procedures and techniques by which the PQI, SR, and PSR are developed can be found in the Mn/DOT Surface Distress Manual, available at: http://www.mrr.dot.state.mn.us/pavement/pvmtmgmt/DistressManual.pdf.

#### **Endnotes for Chapter 3**

<sup>&</sup>lt;sup>i</sup> The actual distance between reference posts is accurately maintained in the database. Numbering of reference posts begins at the state's western or southern border or at the most southerly or westerly terminus of the highway.

Generally, only the outermost lane of multilane highways is measured. Divided highways are considered separate roadways. The 500 feet past each reference post and intermediate changes in pavement type are measured for surface distresses.

This page intentionally left blank.

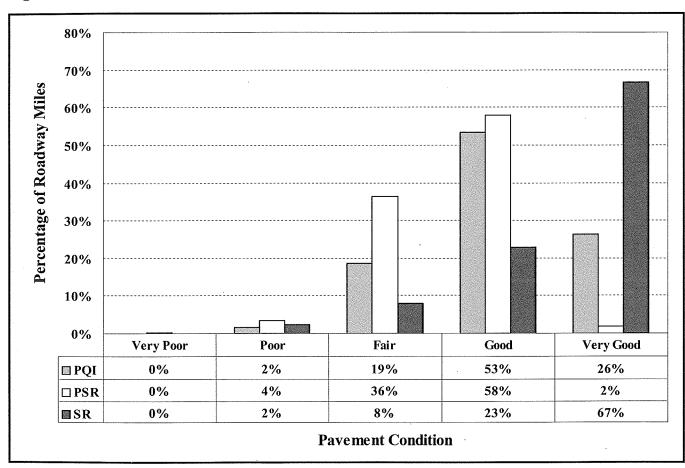

### **Chapter 4 Statewide Conditions**

Figure 4-1 shows the distribution of the current values of the PQI, PSR, and SR into five equal categories: "Very Poor," "Poor," "Fair," "Good," and "Very Good." The category ranges are shown in Table 4-1.

Table 4-1 Descriptive Categories of Pavement Condition

Index	Very Poor	Poor	Fair	Good	Very Good
PQI	0.0 - 0.9	1.0 - 1.8	1.9 - 2.7	2.8 - 3.6	3.7 - 4.5
PSR	0.0 - 1.0	1.1 - 2.0	2.1 - 3.0	3.1 - 4.0	4.1 – 5.0
SR	0.0 - 0.8	0.9 - 1.6	1.7 - 2.4	2.5 - 3.2	3.3 - 4.0

Figure 4-1 Statewide Performance Indices by Performance Classification

Some observations from Figure 4-1<sup>1</sup>:

- O The percent of the trunk highway mileage with a PQI in either the "Good" or "Very Good" category in 2004 is 80 percent, down from 83 percent in 2003.
- O The percent of the trunk highway mileage with a PQI in either the "Poor" or "Very Poor" category in 2004 is 2 percent, up from 1 percent in 2003.

- o The percent of the trunk highway mileage with a PSR in either the "Good" or "Very Good" category in 2004 is 60 percent, up from 59 percent in 2003.
- The percent of the trunk highway mileage with a PSR in either the "Poor" or "Very Poor" category in 2004 is 4 percent, up from 3 percent in 2003.
- o The percent of the trunk highway mileage with an SR in either the "Good" or "Very Good" category in 2004 is 90 percent, down from 91 percent in 2003.

In order to provide more detailed information about the historical shifts in pavement condition, cumulative distribution graphs are shown in Figures 4-2, 4-3, and 4-4 for PQI, PSR, and SR, respectively. These distribution plots show the percentage of roadway miles with an index value equal to or less than the values shown on the horizontal axis. Figures 4-2, 4-3, and 4-4 show the distribution curves for the PQI, PSR, and SR, respectively, for each of the last five years.

Figure 4-2 shows a decrease in overall pavement condition, as measured by the PQI (curve is shifted to the left). The gap is fairly uniform, across the whole range of values, indicating a uniform decline in the system.

Figure 4-3 shows there was no appreciable change in statewide pavement smoothness from 2003 to 2004, as indicated by the PSR (no shift in curve).

Figure 4-4 shows a decrease in the SR from 2003 to 2004 (curve has shifted to the left), especially on the low end, indicating there are more roads with severe cracking in 2004.

Figure 4-2 Cumulative Distribution of Statewide Pavement Quality Index (PQI), 2000-2004

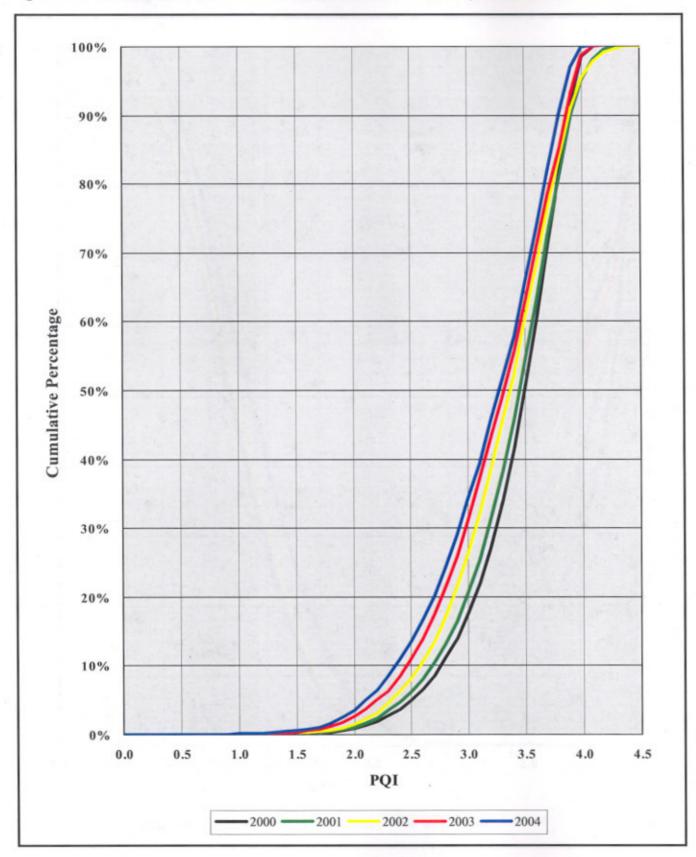

Figure 4-3 Cumulative Distribution of Statewide Present Serviceability Rating (PSR), 2000-2004

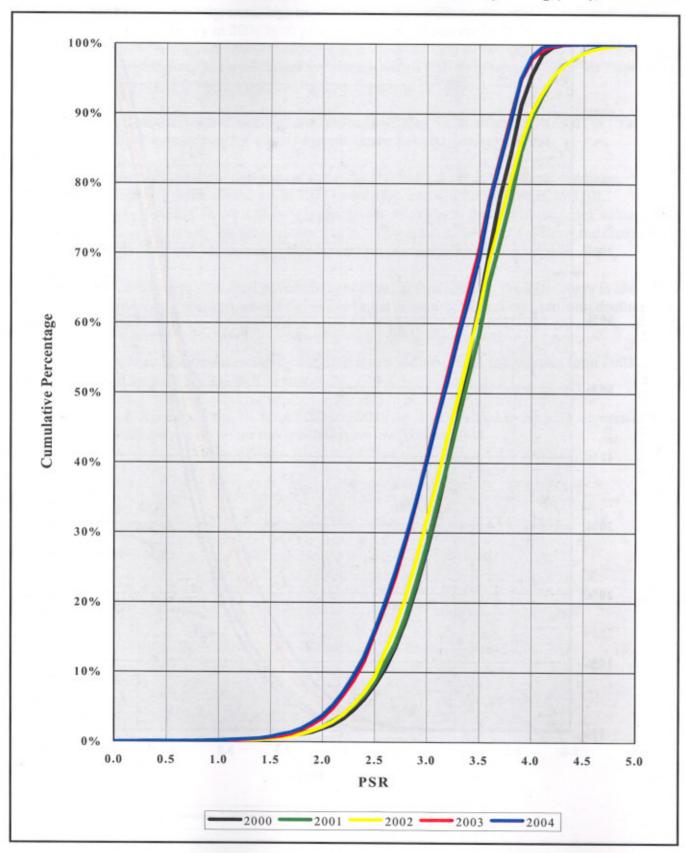

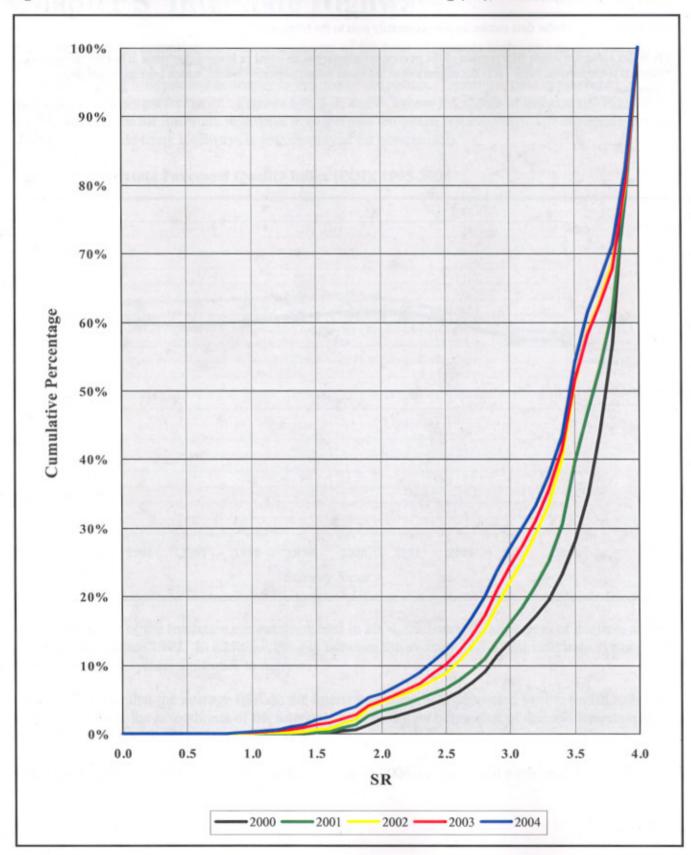

Figure 4-4 Cumulative Distribution of Statewide Surface Rating (SR), 2000-2004

#### **Endnotes for Chapter 4**

Due to rounding, tabular data entries do not necessarily sum to the totals displayed.

The index value for which fifty percent of the pavement mileage has an equal or lower index value is not the mean value. Rather, it is the median value. It is not equivalent to the mean values presented herein, which are length-weighted averages.

### **Chapter 5 Interstate Highways**

Interstate highways comprise only thirteen percent of the total Minnesota highway system roadway miles, but carry nearly forty percent of vehicle miles driven each year. Interstate highways play a major role in connecting Minnesota's economy to the rest of the nation. Therefore, data is presented specifically on their performance. Figures 5-1, 5-2, and 5-3 show the trends of the average PQI, PSR, and SR, and values for interstate highways over the past ten years, respectively. The statewide average of all non-interstate trunk highways is also displayed for comparison.

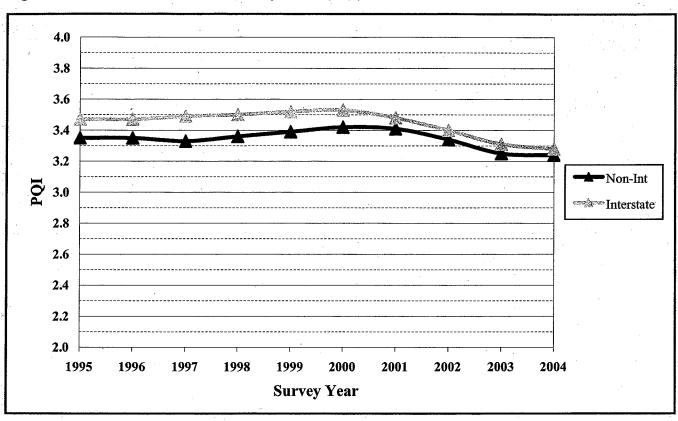

Figure 5-1 Interstate Pavement Quality Index (PQI), 1995-2004

The average PQI of the Interstate system decreased in 2004, the fourth straight year of decline, and is at its lowest level since 1992. In addition, the gap between the average PQI of the interstate system and the non-interstate system continues to narrow.

Figure 5-2 shows that the average PSR on the interstate system also decreased for the fourth straight year. In addition, the smoothness of the interstate system is now below that of the non-interstate system, only the second time this has occurred (1992).

The average SR of the interstate system also declined in 2004 and is now at a ten year low.

Figure 5-2 Interstate Present Serviceability Rating (PSR), 1995-2004

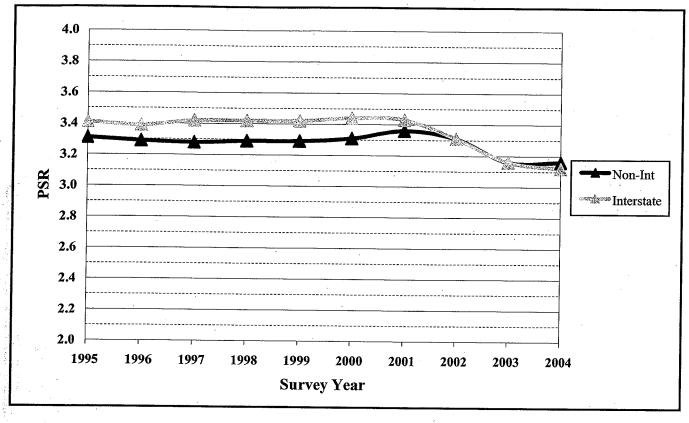

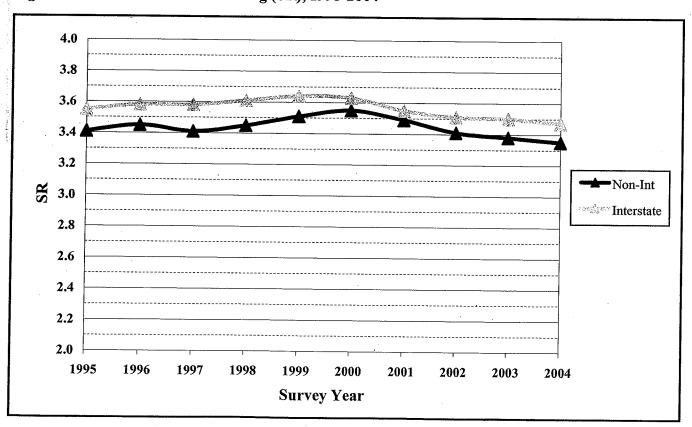

Figure 5-3 Interstate Surface Rating (SR), 1995-2004

## **Chapter 6 District Historical Trends**

To put the current conditions in perspective, it is useful to review historical trends. Figures 6-1 to 6-24 are plots comparing each district with the overall trunk highway system from 1995 through 2004. The statewide average for each year is displayed for comparison. Differences in the relative performance of districts for average index values may be attributable to a higher percentage of high priority functional classes (which have higher trigger values), more severe climatic extremes, or the balance of funds devoted to expansion as contrasted with those allocated to preservation.

Due to the size of the system, the effects of recent actions are relatively difficult to discern regardless of their magnitude. As a result, consistent action or inaction over a long period of time has a profound impact on the current results. To make valid inferences about causal relationships requires that the independent variables be adequately controlled and the data be evaluated over a long enough period of time.

#### **Observations**

District 7 was the only district to show an increase in the average of all three of the pavement condition indices in 2004 (PQI, PR, SR). Districts 2 and 4 showed in increase in two of the three indices (PQI & PSR). Districts 1 and 6 had a decrease in all three of the indices in 2004.

#### Pavement Quality Rating (PQI), Figures 6-1 to 6-8

The 2004 average PQI increased in districts 2, 4, and 7 while it declined in 1, 6, 8, and Metro. D-3 remained virtually the same as in 2004. District 6's average PQI has declined six years in a row, over 11 percent, since 1999, and is now well below any other district. Most of the decline can be attributed to a decline in their average SR (13 percent since 1999), indicating an increase in miles of highway with severe cracking.

#### Present Serviceability Rating (PSR), Figures 6-9 to 6-16

In 2004, the average PSR increased in districts 2, 4, 7, and 8 while decreasing in 1, 3, 6, and Metro. While D-3's average PSR is still slightly above the statewide average it has decreased three years in a row, a decline of almost 9 percent. District 6 has the lowest average PSR, which has declined five straight years.

#### Surface Rating (SR), Figures 6-17 to 6-24

The only district that had an increase in the average SR in 2004 was D-7. This is the third year in a row the average SR has improved in D-7. Since their average SR increased more than their average PSR, much of the increase in SR can likely be attributed to the work of maintenance forces. Districts 2, 3, 4, and Metro remained nearly unchanged. Only D-1, 6, and 8 had any appreciable drop in average SR in 2004. As explained earlier, a drop in SR indicates there are more highways with more total cracking, more severe cracking, or both.
