[7] Order of the Public Utilities Commission dated October 7, 2014 at VI(B), p. 11.

[8] *Id.* at p. 12.

Minnesota Department of Commerce or other Executive action of the State of Minnesota.[9] The obligations of the State of Minnesota are an extension of the Federal trust responsibility owed to Tribal Nations which cannot be met simply by participation of the White Earth Nation and Honor the Earth in the permitting proceedings. The obligation is one of nation-to-nation consultation, and must be done unequivocally and directly with the Tribal Nations. The White Earth Band of Ojibwe advises the Commission that to go any further with permitting of the Sandpiper Pipeline and the Line 3 Pipeline without meaningful consultation and co-management of usufructuary use rights resources is a violation of the trust responsibility.

The White Earth Band of Ojibwe looks forward to meaningful consultation with the State of Minnesota, and development of a co-management plan for usufructuary use rights resources within the 1855 Treaty-ceded territory. And, expects that an Environmental Impact Statement will be completed, considering all routes offered in the Sandpiper proceedings including SA-03, SA-04, SA-05, SA-06, SA-07, and SA-08, as well as all other route and alternative options offered during this scoping period, which considers both the proposal for the Sandpiper Pipeline and the proposal for the Line 3 Pipeline.

The White Earth Band of Ojibwe appreciates the consideration of the Commission in this matter.

Sincerely,

/s/ Joseph Plumer

In the Matter of the Application of Enbridge Energy, Limited Partnership for a *Certificate of Need* and *Pipeline Routing Permit* for the Line 3 Replacement Project in Minnesota

PETITION TO INTERVENE

Docket Nos. PL-9/CN-14-916 and PL-9/PPL-15-137

To: The Minnesota Public Utilities Commission

Pursuant to Minnesota Rules 1400.6200, the White Earth Band of Ojibwe (White Earth Band) hereby respectfully petitions to intervene in the above-referenced Matter of the Application of Enbridge Energy, Limited Partnership for a Certificate of Need and Pipeline Routing Permit for the Line 3 Replacement Project in Minnesota.

Background and Issues

The Applicant, Enbridge Energy, Limited Partnership, applied for a Certificate of Need and Routing Permit for its proposed Line 3 Replacement Project in Minnesota, to be co-located in the corridor selected by the Applicant, Enbridge Pipelines d/b/a/ North Dakota Pipeline Company, LLC, for the proposed Sandpiper Pipeline Project. The proposed corridor for these projects traverses a significant portion of the 1855 Treaty-ceded territory, and goes through the northeast townships of the original White Earth Reservation. The White Earth Band is an intervening party to the Sandpiper Pipeline project proceedings, and has been since 2014. The interest of the White Earth Band in these proceedings is substantially similar to the interests of

White Earth in the Sandpiper Pipeline proceedings given the proposed co-location of these projects and the impact these projects could have on on-Reservation resources and usufructuary use rights resources within the 1855 Treaty-ceded territory.

Identity of Petitioner

The White Earth Band of Ojibwe (the White Earth Nation) is a federally recognized Indian Nation and a constituent member of the Minnesota Chippewa Tribe with its Reservation in west central Minnesota.[1] The members of the White Earth Band are amongst the successors in interest to a number of treaties entered into with the Ojibwe Bands between the 1830's and the 1860's.[2] The members of the White Earth Band hunt, fish, rice, and gather within the Reservation and the 1855 Treaty-ceded territory. The impact of large scale infrastructure energy projects like those proposed by Enbridge Energy, Limited Partnership and the North Dakota Pipeline Company, LLC during both construction and operation may have a significant impact on the health and availability of resources necessary to subsistence and use activities. The protection and health of wild rice within this region of the state is of particular concern to the White Earth Band given its supreme cultural significance to Ojibwe Anishinaabe people, and its importance as a source of food and income.

Argument

I. The State of Minnesota has an obligation to engage in meaningful consultation with the successors in interest to the 1855 Treaty including the White Earth Band of Ojibwe to address the impact of this Project to on-Reservation and off-Reservation usufructuary use rights resources prior to final determinations on the applications for permits.

---

[1] Indian Entities Recognized & Eligible To Receive Services From the Bureau of Indian Affairs, 77 Fed. Reg. 47,868, 47,870 (Aug. 10, 2012).

[2] *See*, Treaty of 1836, 7 Stat. 491 (March 28, 1836); Treaty of 1837, 7 Stat. 536 (July 29, 1837); Treaty of 1842, 7 Stat. 591 (Oct. 4, 1842); Treaty of 1854, 10 Stats. 1109 (Sept. 30, 1854); Treaty of 1855, 10 Stat. 1165 (Feb. 22, 1855); Treaty of 1864, 13 Stat. 693 (May 7, 1864); Treaty of 1867, 16 Stats. 719 (March 19, 1867).

a. The White Earth Band of Ojibwe retains off-reservation usufructary rights in the 1855 Treaty ceded territory which have not been abrogated.

The White Earth Reservation Tribal Council is the governing body of the White Earth Reservation, and is among the successors in interest to the signatories of the 1855 Treaty with the Chippewa (hereinafter "1855 Treaty").[3] Although the 1855 Treaty was a land cession treaty, it did not dispossess the signatories of their retained usufructuary rights in the ceded territory. The Court in *Mille Lacs* noted in its conclusion that the 1855 Treaty did not abrogate previously guaranteed reserved rights. The Court stated:

> The entire 1855 Treaty, in fact, is devoid of any language expressly mentioning-much less abgrotating-usufructuary rights. Similarly, the Treaty contains no language providing money for the abrogation of previously held rights . . . The 1855 Treaty was designed primarily to transfer Chippewa land to the United States, not to terminate Chippewa usufructuary rights.[4]

In addition to the reserved rights provided for in the 1837 Treaty, the 1854 Treaty "also guarantees usufructuary property rights to the Mississippi Chippewa in the *unceded* territory west of the 1854 Treaty boundary . . ."[5] The Mississippi Band was a signatory to the 1854 Treaty, and the 1855 Treaty territory is west of the 1854 Treaty ceded territory.

The retained usufructuary rights of the White Earth Band were intact after the execution of the 1855 Treaty, and have not been subsequently divested.

b. The State of Minnesota is obligated to engage in meaningful consultation with the White Earth Band of Ojibwe regarding the impact of this Project to on and off-Reservation resources including resources within the 1855 Treaty-ceded territory.

---

[3] 10 Stats. 1165 (Feb. 2, 1855). The signatory Bands to the Treaty of 1855 were the Mississippi, Pillager, and Lake Winnibigoshish Bands, whose people were among the Bands that would later organize under the Indian Reorganization Act (48 Stat. 987 (1934) as the Minnesota Chippewa Tribe, which is composed of White Earth, Leech Lake, Mille Lacs, Grand Portage, Bois Forte, and Fond Du Lac.

[4] *Minnesota v. Mille Lacs Band of Chippewa Indians*, 526 U.S. 172, 195, 196 (1999).

[5] Peter Erlinder, *Treaty-Guaranteed Usufructuary Rights:* Minnesota v. Mille Lacs Band of Chippewa Indians *Ten Years On*, 41 ELR 10921, 10930 (Oct. 2011) (emphasis added).

The White Earth Band and other successors in interest to the 1855 Treaty retain usufructuary use rights property interests in the 1855 Treaty-ceded territory.[6] The White Earth Band additionally retains original, sovereign jurisdiction over resources within the Reservation boundaries.[7] As demonstrated in the *Mille Lacs* case, tribes have the authority to regulate their membership within the treaty-ceded territories for the purposes of exercising usufructuary use rights in cooperation with the state agencies.[8] The State of Minnesota is unable to proceed with issuance of the Applicant's Certificate of Need and Routing Permit without the involvement of the White Earth Band and a detailed consideration of the impacts of the proposed project on resources both within the Reservation boundaries and within the 1855 Treaty-ceded territory.

The White Earth Band petitions for intervention in these proceedings as a necessary first step to meaningful consultation with the State of Minnesota for the preservation and protection of on and off-Reservation resources necessary to continued use by the members of the White Earth Band.

Conclusion

The State of Minnesota is required to meaningfully consult with the White Earth Band of Ojibwe regarding the impact of the Line 3 Replacement Project to on and off-Reservation resources, including resources necessary for the continued exercise of usufructuary use rights activities within the 1855 Treaty-ceded territory. The interests of the White Earth Band of

---

[6] *See, e.g.*, Minnesota v. Mille Lacs Band of Chippewa Indians, 526 U.S. at 176 (finding that the Mille Lacs Band of Ojibwe retained usufructuary use rights within the 1837 Treaty-ceded territory including the right to regulate its own membership in the use of such resources).

[7] *See, e.g.*, Worchester v. Georgia, 31 U.S. 515, 557 (1832) (finding that Tribal Nations are "distinct political communities, having territorial boundaries, within which their authority is exclusive. . .").

[8] *Minnesota v. Mille Lacs Band of Chippewa Indians*, 526 U.S. 172, 205 (1999); *United States v. Dion*, 476 U.S. 734 (1986); *Washington et al. v. Washington State Commercial Passenger Fishing Vessel Ass'n, et al.*, 443 U.S. 658 (1979); *Lac Courte Oreilles Band of Lake Superior Chippewa Indians v. Voigt*, 700 F.2d 341, 365 (7th Cir. 1983); and *Lac Courte Oreilles Band of Lake Superior Chippewa Indians v. Wisconsin*, 653 F. Supp. 1420, 1430 (W.D. Wisc. 1987).

Ojibwe in these proceedings are substantially the same as the White Earth Band's interests in the Sandpiper Pipeline Project proceedings. The White Earth Band petitions for intervention in these proceedings to protect the interests of the White Earth Nation and its membership with regard to the continued health and production of on and off-Reservation resources, most important, the health of wild rice. The White Earth Band of Ojibwe does not believe that any other current or prospective party is able to represent and safeguard its interests.

Jamie MacAlister
Environmental Review Manager
Minnesota Department of Commerce
85 7th Place East, Suite 500, Saint Paul, MN 55101

Ms. MacAlister,

Great Lakes Indian Fish and Wildlife Commission (GLIFWC) is an intertribal agency exercising delegated authority from 11 federally recognized Ojibwe (or Chippewa) tribes in Wisconsin, Michigan and Minnesota.[1] Those tribes have reserved hunting, fishing and gathering rights in territories ceded in the 1836, 1837, 1842, and 1854 treaties with the United States (Map 1). GLIFWC's mission is to assist its member tribes in the conservation and management of natural resources and to protect habitats and ecosystems that support those resources.

Enclosed are GLIFWC staff comments on the Draft Scoping Decision (DSD) documents for the Line 3 Replacement Pipeline Project and the Sandpiper Pipeline Project proposed by Enbridge Energy. At this stage of the Environmental Impact Statement (EIS), GLIFWC comments are general in nature. As the process moves forward, we expect that additional comment and interaction with the Minnesota Department of Commerce will occur. GLIFWC submits these comments from an off-reservation Ceded Territory perspective and an individual tribe may choose to submit comments from its own perspective.

---

[1] GLIFWC member tribes are: in Wisconsin -- the Bad River Band of the Lake Superior Tribe of Chippewa Indians, Lac du Flambeau Band of Lake Superior Chippewa Indians, Lac Courte Oreilles Band of Lake Superior Chippewa Indians, St. Croix Chippewa Indians of Wisconsin, Sokaogon Chippewa Community of the Mole Lake Band, and Red Cliff Band of Lake Superior Chippewa Indians; in Minnesota -- Fond du Lac Band of Lake Superior Chippewa, and Mille Lacs Band of Chippewa Indians; and in Michigan -- Bay Mills Indian Community, Keweenaw Bay Indian Community, and Lac Vieux Desert Band of Lake Superior Chippewa Indians.

General Scoping Comments

Analysis of Impacts to Cultural Resources

The DSD Documents indicate that impacts to cultural and natural resources will be analyzed. However, it is important to note that for tribal members, natural resources *are* cultural resources. The Ojibwe have historically used and continue to use their natural resources within the Ceded Territories for spiritual, cultural, subsistence, medicinal and economic purposes. Tribal members harvest and consume freshwater fish, wild rice, and many other natural resources as part of their bimaadiziwin, or traditional lifeway, which incorporates culture, spirituality, language and traditions, including the harvest and consumption of traditional foods. The resources that tribal members depend on have been degraded over time through a combination of loss of access and environmental degradation. Pipelines are one of many constructed features that drastically alter the landscape and can diminish the resources tribes depend on.

The EIS, in its analysis of natural resources (surface and groundwater, wetlands, habitat, etc.) should recognize the importance of a healthy environment to tribes and describe the cultural ties of tribes to the potentially impacted areas of the proposed pipeline projects.

Spatial Extent of Analysis

The Sandpiper line is intended to transport Bakken shale oil from North Dakota to Superior, Wisconsin. Line 3 transports tar sands oil from Alberta Canada to Superior Wisconsin. Therefore, these projects are regional in scope and the impacts of these projects should be described at local and regional scales. We suggest that impacts of all existing pipelines in Minnesota should be done to define existing conditions for these projects. From GLIFWC's perspective, the impacts of pipeline projects on the 1837, 1842, 1836 and 1854 ceded territories should also be conducted (Map 1) with the Ceded Territories used as distinct geographic study areas.

Additionally, on a broader scale, the EIS should also use information developed for other pipeline environmental impact assessments in Wisconsin and North Dakota, and any pertinent information developed for other multi-jurisdictional pipeline projects, such as the Keystone XL project, because these proposals present similar permitting and environmental challenges as the Sandpiper project.

History of Pipeline Safety and History of Enbridge Energy

Enbridge Inc. has a questionable environmental record. From 1999 to 2010, Enbridge pipelines spilled over 7 million gallons of crude oil in over 800 different incidents across the United States and Canada (National Wildlife Federation, 2012). The

combined environmental effect of these incidents to wetlands and surface and ground waters has not been quantified. The most notorious spill involves a ruptured pipeline that spilled over a million gallons of heavy crude oil into the Kalamazoo River in the lower peninsula of Michigan in July of 2010. Thirty-five river miles downstream of the spill were closed by the EPA. Cleanup activities at this site continued until 2014 with costs exceeding 675 million dollars. Cleanup efforts were complicated by the heavy crude oil that, when spilled, sank to the bottom of the river and into the sediment. Line 3 replacement pipeline could transport this type of oil and the proposed Sandpiper pipeline could, potentially, transport heavy crude as well. Because of this, traditional oil cleanup techniques that involve surface skimming of affected waters could be ineffective and costlier dredging of substrates must be performed.

Given this history, the EIS must provide a complete accounting of all spills from pipelines. While it is important that Enbridge's historical operations record is identified, the information should include all companies operating in the region. Spills from local feeder lines should also be detailed. With each pipeline and feeder line operating in the region, the likelihood of spills increases and any cumulative impact of successive spills impacting the region is also potentially greater. This must be acknowledged by the EIS.

Surface and Groundwater Quality

The potential for these pipelines to rupture and cause an oil spill is a major concern. The EIS should document the environmental effects of past oil spills and scientifically assess the effects of a spill in the water rich regions of the Upper Midwest and Lake Superior regions. A systematic assessment of remediation and cleanup techniques must be provided for light and heavy crude oil along with a detailed review of the effectiveness of each technique. The EIS should also quantitatively assess the possible changes to surface and groundwater that may result from a spill.

The water quality assessment should pay special attention to potential impacts to Lake Superior. This analysis should be done in the context of the Great Lakes Water Quality Agreement, the bi-national Water Quality Agreement between Canada and the United States.

A cumulative assessment of all existing impacts from pipeline construction and pipeline spills on surface and groundwater should be conducted.

Wetland Impacts and Wetland Mitigation

Construction and expansion of pipelines involve wetland fill and hydrologic alteration that will affect wetland functions and values. Mitigation for wetland impacts that cannot be avoided will be required. However, the effectiveness of wetland mitigation, both through the use of wetland banks or rehabilitation of drained wetlands, is

questionable. The EIS should describe the effectiveness of wetland mitigation measures and assess whether all functions and values of lost wetlands are likely to be replaced.

Climate Change

Increased oil transportation capacity will contribute to existing CO2 emissions into the atmosphere and exacerbate global climate change. Potential impacts of climate change have been documented for the Ceded Territories through work of the Wisconsin Initiative on Climate Change Impacts (WICCI) and GLIFWC (Attachment 1). Potential impacts on the Lake Superior Basin have been described through the work of the Lake Superior Workgroup. Furthermore, the impacts on forest ecosystems have been described by the Northern Institute of Applied Climate Science (NIACS) of the USDA. The EIS should examine the effects that this project will have on carbon emissions as well as the effect on the climate change adaptation strategies that have been suggested for Minnesota and the Lake Superior region.

The DSD documents for both projects indicate that regional economic analysis of the effects of the projects will be conducted. These economic analyses should include information on the economic effects of climate change on the region and account for the contribution of the pipeline projects to these impacts.

The economic analysis should also describe treaty guaranteed usufructury rights of Tribes in the region and assess how the proposed pipeline projects would impact the ability of tribes to continue to exercise their rights.

Financial Assurance

As previously discussed, GLIFWC staff believe that spills of oil transported through these pipelines are likely. Cleanup and remediation are costly and require long periods of time to complete. The EIS should describe, in detail, the types of financial assurance that Enbridge will be required to provide to ensure that the public is not burdened with cleanup and remediation costs. Furthermore, financial assurance is needed to cover the costs of maintaining structural integrity of the abandoned Line 3 as well as the costs of ultimately removing pipelines from the right of way whenever that becomes feasible.

No Action Alternative

The no action alternative for the proposed Sandpiper project assumes that Bakken oil will continue to be shipped by other means. The assumption that oil extraction at current levels will continue to be necessary is not supported. The United States has decided against approving the Keystone XL pipeline. There are many reasons for this, but concerns over increased carbon emissions and their contribution to global climate change as well as concerns over accidental releases of oil are two of the most important reasons.

This same rationale applies to the proposed new Sandpiper line. The analysis in the EIS should acknowledge that the need for oil transported by the Sandpiper line and Line 3 is speculative and that this oil may not be needed nor desired, given the commitments the United States has made on climate change mitigation.

Cumulative Impact Analysis

In general, the description of cumulative impact analysis is appropriate. However, there are some points that should be clarified.

Page 13 of the Line 3 Replacement DSD document states:

> "Each project will have its own EIS, and the cumulative impacts of each project will be addressed in both EISs."

Page 15 of the Sandpiper Pipeline DSD Document states:

> "The Sandpiper EIS will analyze the potential impacts of the L3R Project as part of the EIS's cumulative impacts discussion. In addition, other projects throughout the Sandpiper corridor that may cause cumulative impacts will also be discussed at a local, county and larger regional levels."

Cumulative effects analysis must not be confined to the corridor of the pipeline projects. The analysis of cumulative effects should be broad enough to account for regional impacts such as habitat fragmentation and wetland fragmentation. Additional clarity on the spatial extent of the cumulative impact assessment is needed.

The EPA, in cooperation with Region 5 tribes, has developed a protocol for assessing cumulative effects on tribal resources. This guidance should be used in the EIS for the proposed pipeline projects.

Impacts of Routine Construction and Operation

The DSD documents for Sandpiper and Line 3 projects discuss the impacts of routine construction and operation activities. However, additional detail is needed to clarify the scope of the analysis. The EIS must describe the impacts of all activities related to pipeline maintenance into the future. This includes impacts from permanent and temporary access roads and activities needed to maintain cathodic protections in pipelines abandoned in place. The EIS must anticipate, based on past experience, all permits that the applicant will need over the lifetime of the pipelines and describe them in detail.

We look forward to working with the Minnesota Department of Commerce as the EIS process moves forward. Please contact me at 608-263-2873 with any questions.

Sincerely,

Esteban Chiriboga

Preliminary Climate Change Vulnerability Assessment for the Ceded Territories

Introduction

Sound conservation practices and management decisions are vital to GLIFWC's core mission of protecting and enhancing natural resources in the ceded territories. Climate data have shown that average temperature and precipitation in the ceded territories have been changing since the mid-1950's at least. These changes are due to increased greenhouse forcing in the atmosphere associated with the burning of fossil fuels. These rapid climate changes are, at best, another stressor on the ecosystems that tribes depend upon to exercise their treaty rights. At worst, these climate changes are a direct threat to the continued existence of treaty-protected natural resources that tribal members depend upon. GLIFWC has begun the process of assessing the predicted effects of climate changes on ceded territory ecosystems with the ultimate goal of developing a climate change adaptation strategy. This strategy will outline the conservation and management practices that can be implemented to protect traditional resources. It is important to note that climate change adaptation is a temporary measure that may reduce some of the impacts of climate change. The only permanent solution is to reduce the emissions of fossil fuels to the atmosphere.

This vulnerability assessment is the first step in developing an adaptation. It characterizes the potential climate changes expected within the Ceded Territory (e.g. temperature, precipitation, snow cover, etc.). It is important to note that this analysis treats the ceded territories as a distinct geographic unit and it is this ceded territory unit that is the focus of the study. The potential effects of climate change on a subset of species that GLIFWC member tribes harvest is also provided to add context to changes that the ceded territory is likely to experience. Finally, recommendations for additional, more detailed, risk assessment analyses are presented.

Predicted Climate Changes to the Ceded Territory

Temperature and precipitation are the driving variables in regional climate change research and are the basis of this vulnerability assessment. From those 2 variables, other factors that affect the ceded territory ecosystems like snow (quantity and timing), soil moisture, growing degree days, can be computed. This report relies on 2 datasets to examine the vulnerability of the ceded territory to predicted climate changes -- the National Center for Atmospheric Research (NCAR) and the Wisconsin Initiative on Climate Change Impacts (WICCI) downscaled climate change databases. Both the NCAR and WICCI datasets are computed by statistically downscaling the output of global climate change models (GCM). The underlying models used in the downscaling procedure are different for NCAR and WICCI, but at a ceded territory scale, the results are very similar. This dataset cross-check increases the confidence that the downscaling procedure is valid.

It is important to note that the downscaled climate change predictions that are the basis of this report are not without uncertainty. There are general conclusions that can be made with a great deal of scientific confidence. First, the climate of the Ceded Territories has changed and will continue to change in the future. Second, these changes are the result of enhanced greenhouse effect in the atmosphere that is caused by human emissions of carbon. Third, these climate changes, will have profound effects on plants and animals because these changes are occurring faster than ecosystems can change. What is uncertain, is the precise changes that will occur and the exact consequences that climatic changes will bring. Research in these areas is ongoing. For example, downscaled models of temperature and the associated vegetation shift have a greater degree of confidence that downscaled models of precipitation and lake levels. This report presents the best available information for the Ceded Territories in order to provide a preliminary assessment of changes and stresses to the ecosystems of the region.

This vulnerability assessment looks at predicted changes to ceded territory climate variable under two different global climate change scenarios -- A1 and A1B. These two scenarios were selected because, based on current carbon emission trends, they appear to be likely to occur in the future. The scenarios are defined by the Intergovernmental Panel on Climate Change (IPCC) as:

- A2. The IPCC A2 scenario describes a future world of intense fossil fuel use, rapid economic growth, global population that reaches 10 billion by mid-century, and the slow introduction of new and more efficient technologies. Major underlying themes are regional economic development and a lack of international cooperation. It can be considered a high emissions scenario.
- A1B. The IPCC SRES A1B scenario is marked by a balance in the use of fossil fuels and renewable energy sources. It is often thought of a mid-level scenario. It assumes very high economic growth and relatively low population growth . A convergence of global living standards results in a high per-capita demand for food, fiber, and energy. As a result, there is an increase in the human footprint on the landscape, with a decline in natural land covers such as grassland, forest, and wetland.

Changes to temperature and Precipitation are analyzed for the end of the 21st century (2099). While annual averages of temperature and precipitation are important in defining the scale of changes, considerable attention is given to the expected changes in climate during winter (monthly averages of December, January, February), Spring (monthly averages of March, April, May), Summer (monthly averages of June, July, August), and Fall (monthly averages of September, October, November). These seasonal changes are important in characterizing effects on the many seasonal activities in which tribal members engage.

Predicted Temperature Changes

Temperatures are expected to increase throughout the ceded territory. By the end of the century, average annual temperatures are predicted to increase on average across the Ceded Territories by approximately 4^{o}F under the A1B scenario (Map 1) and 5^{o}F to 6 ^{o}F under the A2 scenario (Map 2).

There are no significant seasonal differences in the magnitude of warming at a ceded territory scale The data indicate that greater warming is associated with the high emissions scenario.

Table 1: Predicted Seasonal Temperature Changes in the Ceded Territories by the End of the Century:

Emissions Scenario	Winter	Fall	Summer	Spring
A1B	2.7°F to 3.5°F	3.1°F to 4.1°F	2.7°F to 4.2°F	2.3°F to 3.4°F
A2	5.1°F to 6.9°F	4.8°F to 6.3°F	4.3°F to 6.8°F	3.4°F to 5.1°F

Interesting spatial patterns can be detected from the seasonal temperature data. During winter, the 1837 ceded territory is predicted to warm less than other ceded territories. This pattern is evident for both emission scenarios (Map 3 and 4). Maps for the Fall (Map 5 and 6) and Summer seasons (Map 7 and 8) indicate that the 1854 and 1837 ceded territories are predicted to warm more than the 1842 and 1836 ceded territories. This pattern is likely the result of Lakes Superior and Michigan moderating temperatures. The lakeshore areas and areas downgradient of the prevailing wind patterns are predicted to warm less than the areas upgradient of the lakes. Model predictions for the Spring season (Map 9 and 10) show different spatial patterns for the A1B and A2 scenarios. While springs are expected to be warmer, greater warming is expected in the western half of the ceded territories under the A1B scenario. The opposite prediction is evident during the A2 scenario. Spring is a notoriously difficult season to model because of the rapid changes that occur in the transition from snow and ice cover conditions to a dynamic growing season. The predictions are also complicated by the fact that there will be fewer days of snow and ice cover over the winter. Additional data are needed to provide greater clarity to spring season predictions.

Predicted Precipitation Changes

Precipitation is expected to increase throughout the ceded territories by the end of the century under both the A1B and A2 modeling scenarios (Map 11 and 12). The annual average increases are relatively small and the spatial pattern is the same for both emission scenarios. The modest increases in precipitation combined with the expected temperature increases suggest that the ceded territories are predicted to become drier as the evaporation potential created by the increased temperatures exceeds the additional precipitation.

Table 2: Predicted Seasonal Precipitation Changes in the Ceded Territories by the End of the Century

Emissions Scenario	Winter	Fall	Summer	Spring
A1B	0.3" to 0.9"	0.1" to 1.1"	0.2" to 1.8"	0.5" to 2.4"
A2	0.7" to 1.8"	0.5" to 1.5"	0.4" to 2.2"	0.5" to 1.6"

Downscaled model predictions of winter (Map 13 and 14) and fall (Map 15 and 16) precipitation indicate small increases and the predicted changes do not constitute significant deviations from existing

conditions at a ceded territory scale. At more detailed scales, topography and microclimates, including seasonal wind patterns, could have dramatic effects on precipitation patterns and their changes. Additional work in this area is needed. Summer precipitation is predicted to increase for both the A1B and A2 scenarios (Map 17 and 18). Under both scenarios, the models indicate that precipitation increases, if any, would be the smallest in the northern half of the ceded territory and increase to the south of Lake Superior. Large storm events are predicted to increase so the increased precipitation may come in the form of large storm events with drier periods in between. When combined with the temperature predictions it is reasonable to assume that conditions by the end of the century may be drier overall. Spring precipitation is also predicted to increase (Map 19 and 20) but As described in the temperature section, Spring is a difficult season to model because of the rapid changes that occur in the transition from snow and ice cover conditions to a dynamic growing season. Additional research is needed to provide greater clarity to spring season predictions.

Predicted Snowfall Changes

New research and downscaled modeling indicates that annual mean snowfall is expected to decline throughout the ceded territories. In addition, the beginning of the snow season is expected to occur later in the year and snowmelt is expected to occur earlier in the year. Thus, the duration of snow cover will decrease throughout the region. Individual snowstorms are predicted to become less common but more intense. Map 21 illustrates the predicted reduction in snow depth by comparing the average winter snow depth for the present, mid-21st century and late 21st century time periods. The location of the modeled 15 centimeter snow depth contour retreats to the north over time. By the end of the 21st century, the 15 centimeter contour is located almost entirely outside the ceded territory.

Predicted Change in the Frequency of Extreme Precipitation Events

Extreme precipitation events are expected to become more frequent. This is particularly important for the long term stability of existing infrastructure and of large-scale projects like metallic mines. Mines leave behind large tailings basins and waste rock stockpiles that become permanent features of the landscape. These facilities were designed and constructed with tolerances for climate extremes that will not exist in the future. New mines must incorporate additional safety and structural tolerances to account for increased climatic stresses. Extreme events will also likely impact natural ecosystems through increased flooding events, droughts, erosion, etc. Additional work is needed to characterize the effect these events may have on natural resources in the ceded territory.

Climate Change and Manoomin (Wild Rice)

Manoomin is highly important to the traditional lifeway and has a key role in Ojibwe history. The Sokaogon Chippewa Community established the location of their reservation because of the importance of Rice Lake to the band. The annual harvest of rice is a major event in the tribal year. Because of its unique characteristics, wild rice may be particularly vulnerable to climate change-related impacts.

Manoomin (Wild rice) Life Cycle (information from Peter David, GLIFWC Manoomin Biologist)

- Wild rice is an annual, cross-pollinated species.
- It generally grows in muddy shallow areas of lakes and streams.
- Wild rice requires about 2600 growing degree days (4.4° C base).
- Grows effectively in depths ranging from 6 to 36 inches (ranges are approximate) and site-specific hydrology is very important.
- Natural stands are found in water with <10 ppm of sulfate.
- Wild rice requires a certain amount of water flow,

Germination – Germination begins in late April to early May when the soil/water reach 5.6° C. During the seedling stage the leaves are submerged.

Some factors affecting plant growth:

- Turbidity/light penetration.
- Water Temperature
- Plant Competition and Shading
- Water Depth

Floating Leaf Stage – In May and early June, the next set of leaves that appear after the submerged seedling stage float on the surface of the water. All subsequent leaves are aerial.

Some factors affecting wild rice at this stage:

- Large storm/wave events can uproot the plant.
- Increased water level can drown the floating leaves.
- Herbivory by muskrat, deer, geese and swans.

Emergent Leaf Stage – In late June to early July additional aerial leaves and the main stem appear. This stage occurs earliest in shallow waters and later with increasing depth.

Some Factors affecting wild rice at this stage:

- Herbivory by muskrat, deer, geese and swans.
- Possible hail damage.

Flowering Stage – Flowering occurs in July. Pollen viability appears to be negatively correlated with temperature and positively correlated with humidity. In late July and August tillers begin to emerge and their maturity lags roughly 7 to 14 days behind the growth of the main stem. During August the grain is at an early stage of development.

Some factors affecting wild rice at this stage:

- Hot dry calm days at time of pollen release may hinder fertilization success and reduce seed set.
- Rice worm infestation (noctuid moth larva) can reduce seed yield by 10% per larva.
- Wind storms can knock the plant over or tissue can be damaged by hail.
- Drought can leave plants on exposed soil, stressing the plant in several ways.

Maturation Stage – Seeds mature and drop from the plant from late August through mid to late September. After dropping, the grains sink and are generally deposited in the sediment near the parent plant. Seeds will not germinate for at least 3 months after dropping and require a dormant period in water at or near freezing (<=35). The seed lies dormant in the sediment until the following spring when roughly 50% of the seed will germinate. Approximately 10% of the seed can remain dormant for up to 5 years, possibly longer.

Some factors affecting wild rice at this stage:

- Excessive sedimentation. Seed buried under >8 centimeters results in no emergence.
- Mild winters may contribute to poor rice season because the dormant period is too warm and because of the possibility of increased rice worm infestation.
- Over-winter drought conditions might lead to seed desiccation.

Other Concerns

- Climate change may alter wild rice's ability to compete with various species, including invasives.
- Brown spot (formerly called *Helminthosporium* brown spot) is the most serious disease affecting wild rice. This disease is caused by *Bipolaris oryzae* Luttrell (*Helminthosporium oryzae* B. de Haan) and *B. sorokiniana* Luttrell (*H. sativum* P.K. and B.). These fungi are considered to cause brown spot since both are found on infected plants and cause similar symptoms in wild rice plants. Every variety of wild rice, at each stage of development, is susceptible to brown spot. This disease is most severe when day temperatures range from 77 to 95° F and nights are 68° F or warmer. High relative humidity (greater than 89%), and the continuous presence of free water on leaf surfaces for 11 to 16 hours, can also favor infection. All parts of the plant are susceptible to infection.

Climate Change Parameters Important in Detailed Vulnerability Assessment:

GLIFWC staff developed an initial list of parameters that may be used in a detailed climate change vulnerability assessment for wild rice. The parameters are listed below.

Brown Spot Disease:

- Change in frequency of 77 to 90+ degree days.
- Change in frequency of night temp of 68 F or warmer.
- Change in frequency of relative humidity (>89%)

Risk of Uprooting:

- Change in frequency of 20 year flood events

Germination Success:

- Changes in winter temperature (more mild winters)
- Increased regional drought leading to lower water levels

Changes in Plant Competition

- Increase in number of growing degree days favor southern species

Risk of Pollination Failure -

- Increase in frequency of dry weather in July/August?

Map 22 indicates that by the end of the century summers in the western half of the ceded territory are predicted to be 5.9°F to 6.8°F warmer than current conditions under the A2 emissions scenario. Map 23 indicates that summers are predicted to warm between 2.7°F to 4.2° across the ceded territory, with the eastern half of the ceded territory predicted to warm somewhat less than the western half. All wild rice waters depicted in the map could be affected, but some areas may more severely impacted. As outlined above, brown spot disease is likely to become more common as the climate warms. The increase in extreme precipitation events will contribute to uprooting of plants during the floating leaf stage. At the same time, an overall drier climate may reduce pollination success. Additional work is needed to assess the effects on individual rice waters and the effect of the various climatic factors on the plant in increased spatial detail. The overall conclusion is that wild rice is vulnerable throughout the ceded territories with increased vulnerability on the western half of the region. It is possible that wild rice beds along the coast of Lake Superior may be sheltered from temperature-related impacts but the effects of Lake Superior level changes should be characterized.

Climate Change and Cold Water Ogaa (Walleye) Fishery

Coldwater habitats are defined by their maximum seasonal water temperatures (17 degrees Celsius during June and August). In general, rising air temperatures will be associated with rising lake and stream temperatures as well. Increasing temperatures have the potential to change coldwater habitats to cool water or even warm water habitats, subsequently affecting the ecology and species composition in lakes or rivers.

The spring walleye spearing season begins immediately after ice-out in inland lakes. Predicted spring temperature changes are likely to cause earlier ice out. Maps 24 and Map 25 indicate that the temperature of the air above many of the inland walleye lakes that are open for tribal spearing is predicted to warm between 2.3°F and 5.1°F during the spring season depending on the emissions scenario. Maps 26 and 27 characterize summer impacts to trout streams. Brook trout are among the most vulnerable species to water temperature increases because their habitat consists of shallow cold streams, which are highly affected by changes in air temperature. The maps indicate that some streams in the ceded territory are more vulnerable than others. Under both scenarios, the western end of the ceded territories is predicted to have greater impacts on coldwater habitats than the eastern side. However, the future water temperature in the individual walleye lake and trout stream will depend on many other factors, such as the health and quality of riparian environments and the amount of groundwater in the water budget for each individual waterbody.

Research conducted by the coldwater fisheries working group of WICCI indicated that brook trout, walleye and northern pike habitat is expected to decline throughout the ceded territory. However, at a ceded territory scale it is not possible to assess lake-specific vulnerability because lake temperatures in many cases are moderated by groundwater inflow, differences in lake morphology, and the characteristics of riparian zones. For example, deep natural lakes will warm less than shallow ones. Also, the degree of dependence of a lake on groundwater, its shape and depth, and the character of shorelines and riparian habitat will ultimately determine the water temperature increase and the viability of coldwater fish species. Trout streams with abundant shade trees will warm less than exposed stream banks. Generally, cold and cool water fish species are vulnerable to climate change, and vulnerability is greater in rivers, streams and shallow lakes. Additional work is needed to characterize vulnerability on a lake by lake basis because of the implications that climate change has on the different tribal activities that occur in the ceded territories. For example, it is known that lakes in the western side of the ceded territories are the first to thaw in the spring and therefore, tribal walleye spearing activities occur there and moves eastward as those lakes lose ice cover. If the eastern ceded territory warms at a faster rate, this pattern may change.

Climate Change and Mooz (Moose)

Moose habitat includes boreal forests and subarctic mixed forests. The southern limit of moose range coincides with the northern limit of the ceded territories for GLIFWC member tribes in Wisconsin and Michigan and have populations in northern MN and upper MI. Moose have specific temperature tolerances and prefer areas where the average summer temperature does not exceed 60°F and winter temperatures that do not exceed 41°F. Because of this, moose are easily heat stressed, and the effects of climate change upon moose are likely to be greatest in the southern limits of their range where temperatures and exposure to white-tailed deer parasites and ticks are greatest. Moose populations in Minnesota have declined substantially in recent years, and this decline has been correlated with increasing temperatures. In the Upper Peninsula of Michigan, recent population estimates suggest the growth rate of this re-introduced population may have slowed in recent years. The decline in moose populations are attributed to summer heat stress, increased mortality from parasites (more ticks survive in mild winters), and brain parasites carried by white tail deer. Maps 28 and 29 indicate that current moose ranges are in areas that are predicted to warm the most in the future for both emission scenarios. This suggests that winter stress from ticks will only increase. Maps 30 and 31 suggest summer indicating that summer heat stress will continue to be a problem throughout the ceded territories regardless of emission scenario. However, the moose range in the 1854 ceded territory is predicted to be more severely impacted than the moose ranges in the Upper Peninsula of Michigan. Regardless of the emissions scenario, the future of moose in the Ceded Territories seems uncertain.

Climate Change and Makwa (Black Bear)

Black bear habitat is found throughout North America in areas without significant urbanization. Because of their large range it is unclear how climate change may affect this species. Bears hibernate during the winter months when food is scarce; in the ceded territories, changes in temperature and shortening of the winter season are likely to change the timing of winter hibernation. Additionally, bears typically leave the den when ambient temperature is above 50°F and snow is melting; this melting condition is predicted to occur earlier in the year, which may cause bears to emerge from hibernation before food is available. Map 32 and 33 depict the location of selected hibernacula and bear management zones where GLIFWC issues permits. The map indicates that spring temperatures are predicted to increase for both emission scenarios across the range of black bears in the ceded territories. It is therefore expected that bears will emerge from hibernation earlier in the year across all management zones. Additional research is needed to determine if this change in timing of hibernation is harmful to bear health, or if climate change will affect black bears in any other ways, such as impacts on food sources, access to water, etc.

Climate Change and Waabezheshi (American Marten) and Ochig (Fisher)

American Marten and Fisher are found in suitable habitats throughout the ceded territories. In the Wisconsin and Michigan ceded territories the Marten and Fisher are at the south fringe of their ranges and both species are sensitive to warm temperatures. The southern extent of the fisher range is determined by temperature. Aside from heat stress, a changing climate may provide fishers a competitive advantage over martens, because fishers appear to use a larger variety of forest cover types than martens. However, deep fluffy snow may give pine martens a competitive edge over fishers as well as thermal protection over the winter; the small rodents on which martens feed also need fluffy snow cover. The predicted reduction in winter snow cover (map 21) may allow fishers to outcompete martens throughout the ceded territory. Additional research is needed to fully characterize the effect that warmer temperatures and reduction of snow cover may have on these two species as well as the competitive relationship between them. In addition, both species have preferences for specific types of forest cover. The effect of climate change on those ecosystems should be assessed in greater detail.

Climate Change Parameters Important in Detailed Vulnerability Assessment:

- Change in temperature for summer and winter
- Change in snow depth
- Change in snow density
- Change in seasonal duration of snowpack
- Increased variability of spring temperature and precipitation. (Creates thawing and refreezing of snow which increase density.

Climate Change and Forest Species

Climate change is expected to affect the suitable habitat of tree species impacts to northern tree species are expected to lead to a conversion to other types of forests that are more common in southern parts of the country. This conversion is detailed in work conducted by the US Forest Service Northern Research Station. Three species are listed in this vulnerability assessment because of their importance to GLIFWC member tribes. The information is taken from the USDA tree atlas at http://www.fs.fed.us/nrs/atlas/. Additional information for other tree species is available at this site.

Wiigwaas (Paper Birch)

The historic range of paper birch encompasses the entire Ceded Territories (Map 34). Recently, a decline has been noted in populations of paper birch, potentially due to changes in climate. "Higher soil temperatures, windstorms and the arrival of new forest pests such as mountain pine beetles would impact almost every tree species found in the north woods today. Paper birch and Aspen would decline from increased drought. White cedar and white pine regeneration would be impacted by deer herds that expand thanks to milder winters".

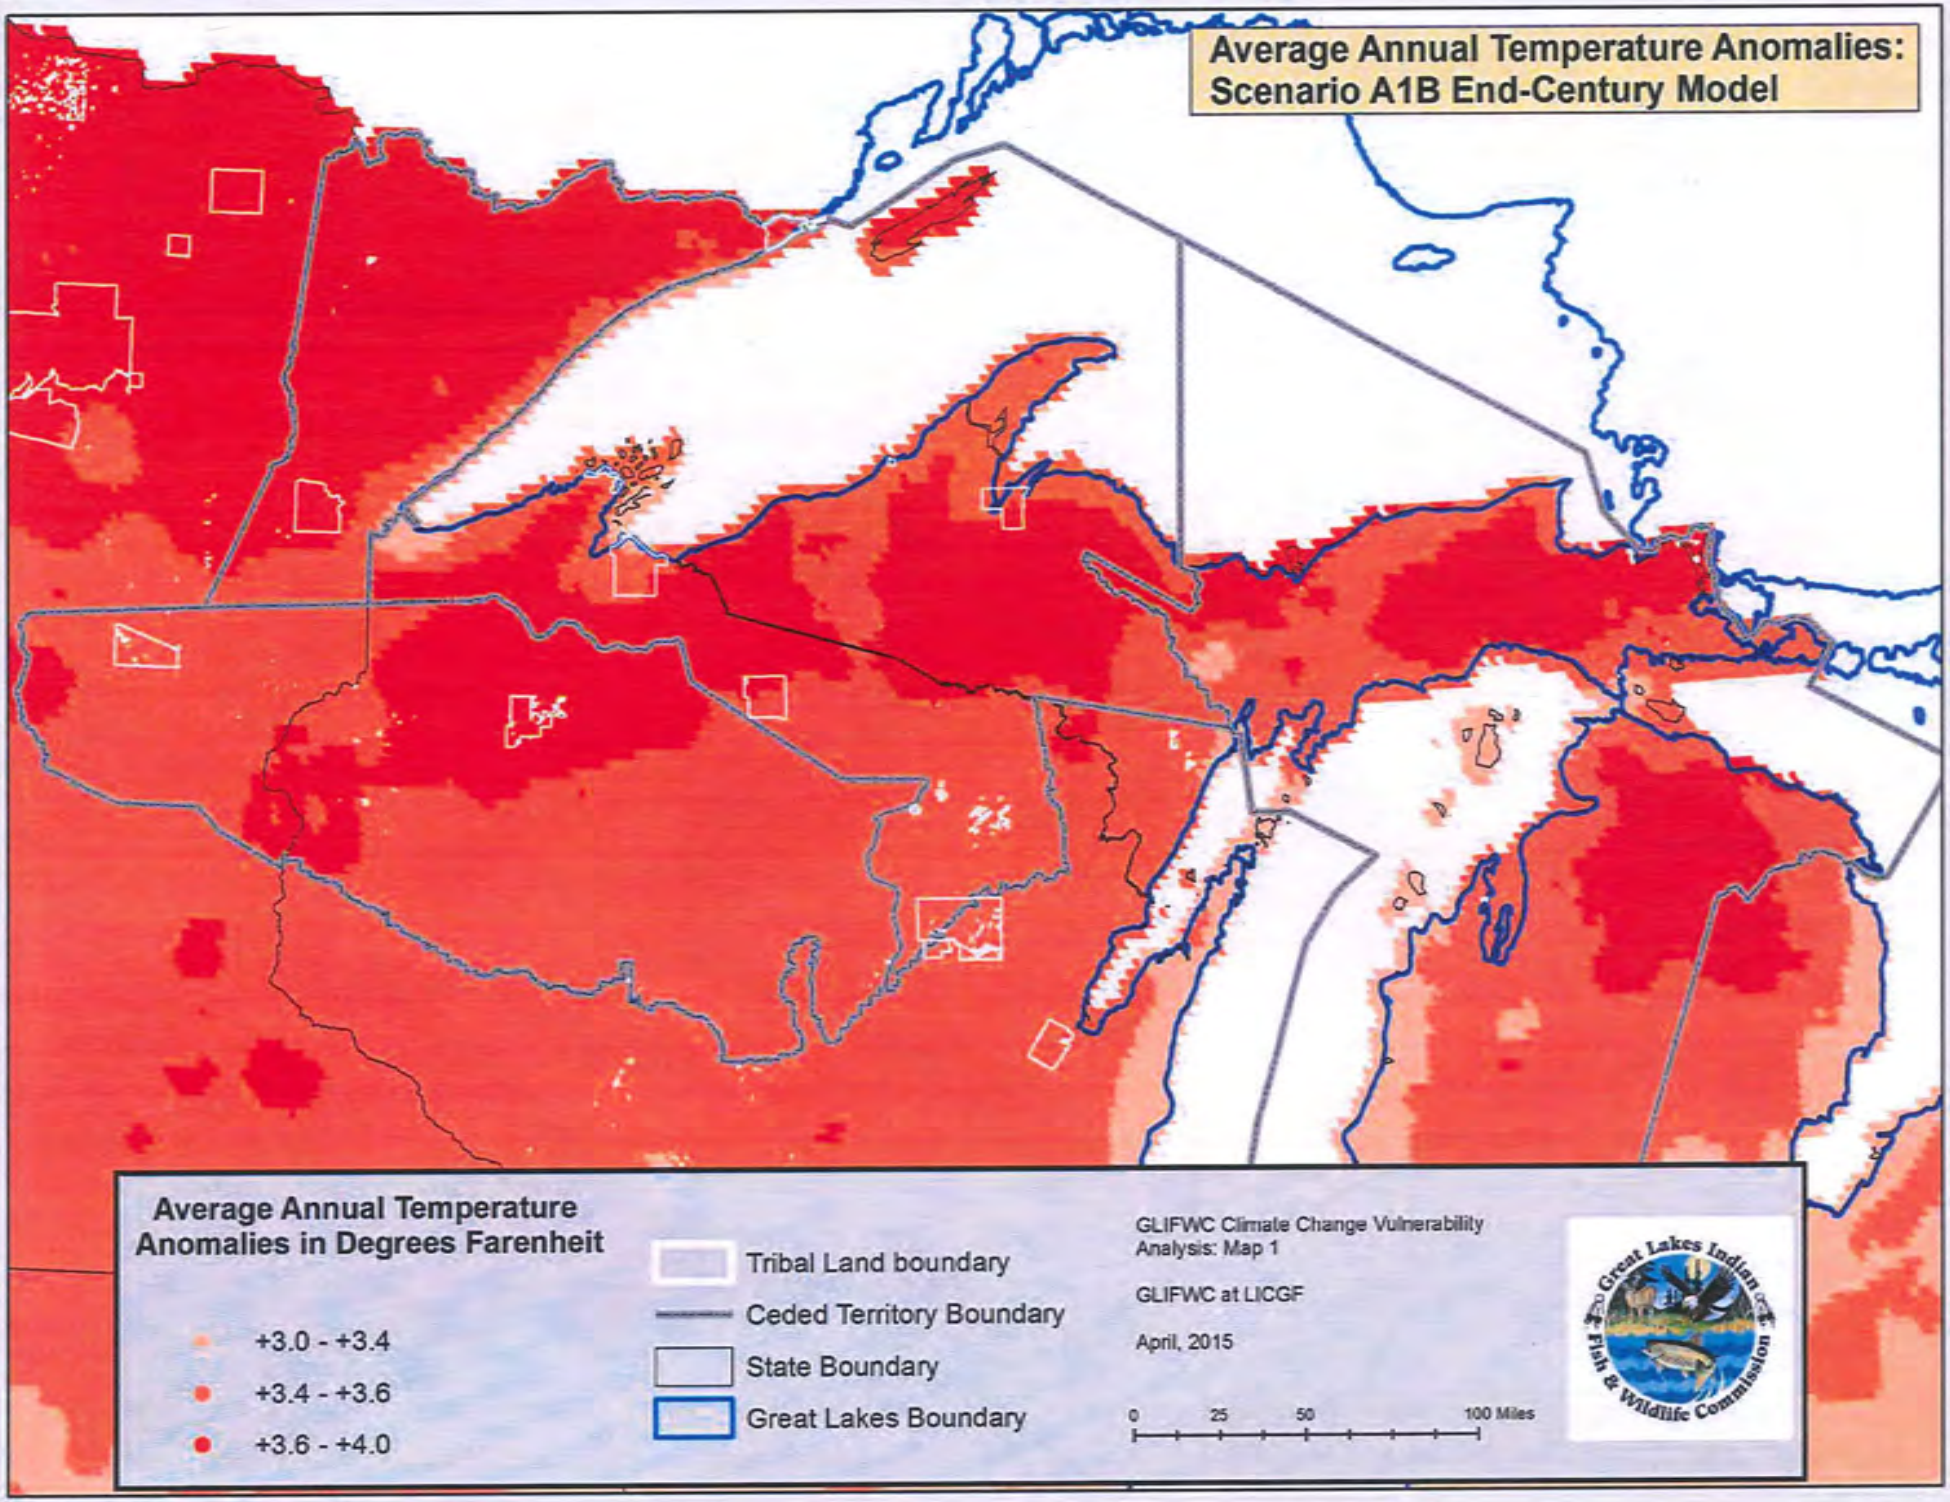
Paper birch is expected to decline in the ceded territories by between 58 and 87 percent depending on the emissions scenario (Maps 35 and 36). Paper birch are known to be fairly drought-intolerant, sensitive to higher temperatures, and dependent on productive soils. This is one of the species most severely impacted in the models.

Aninaatig (Sugar Maple)

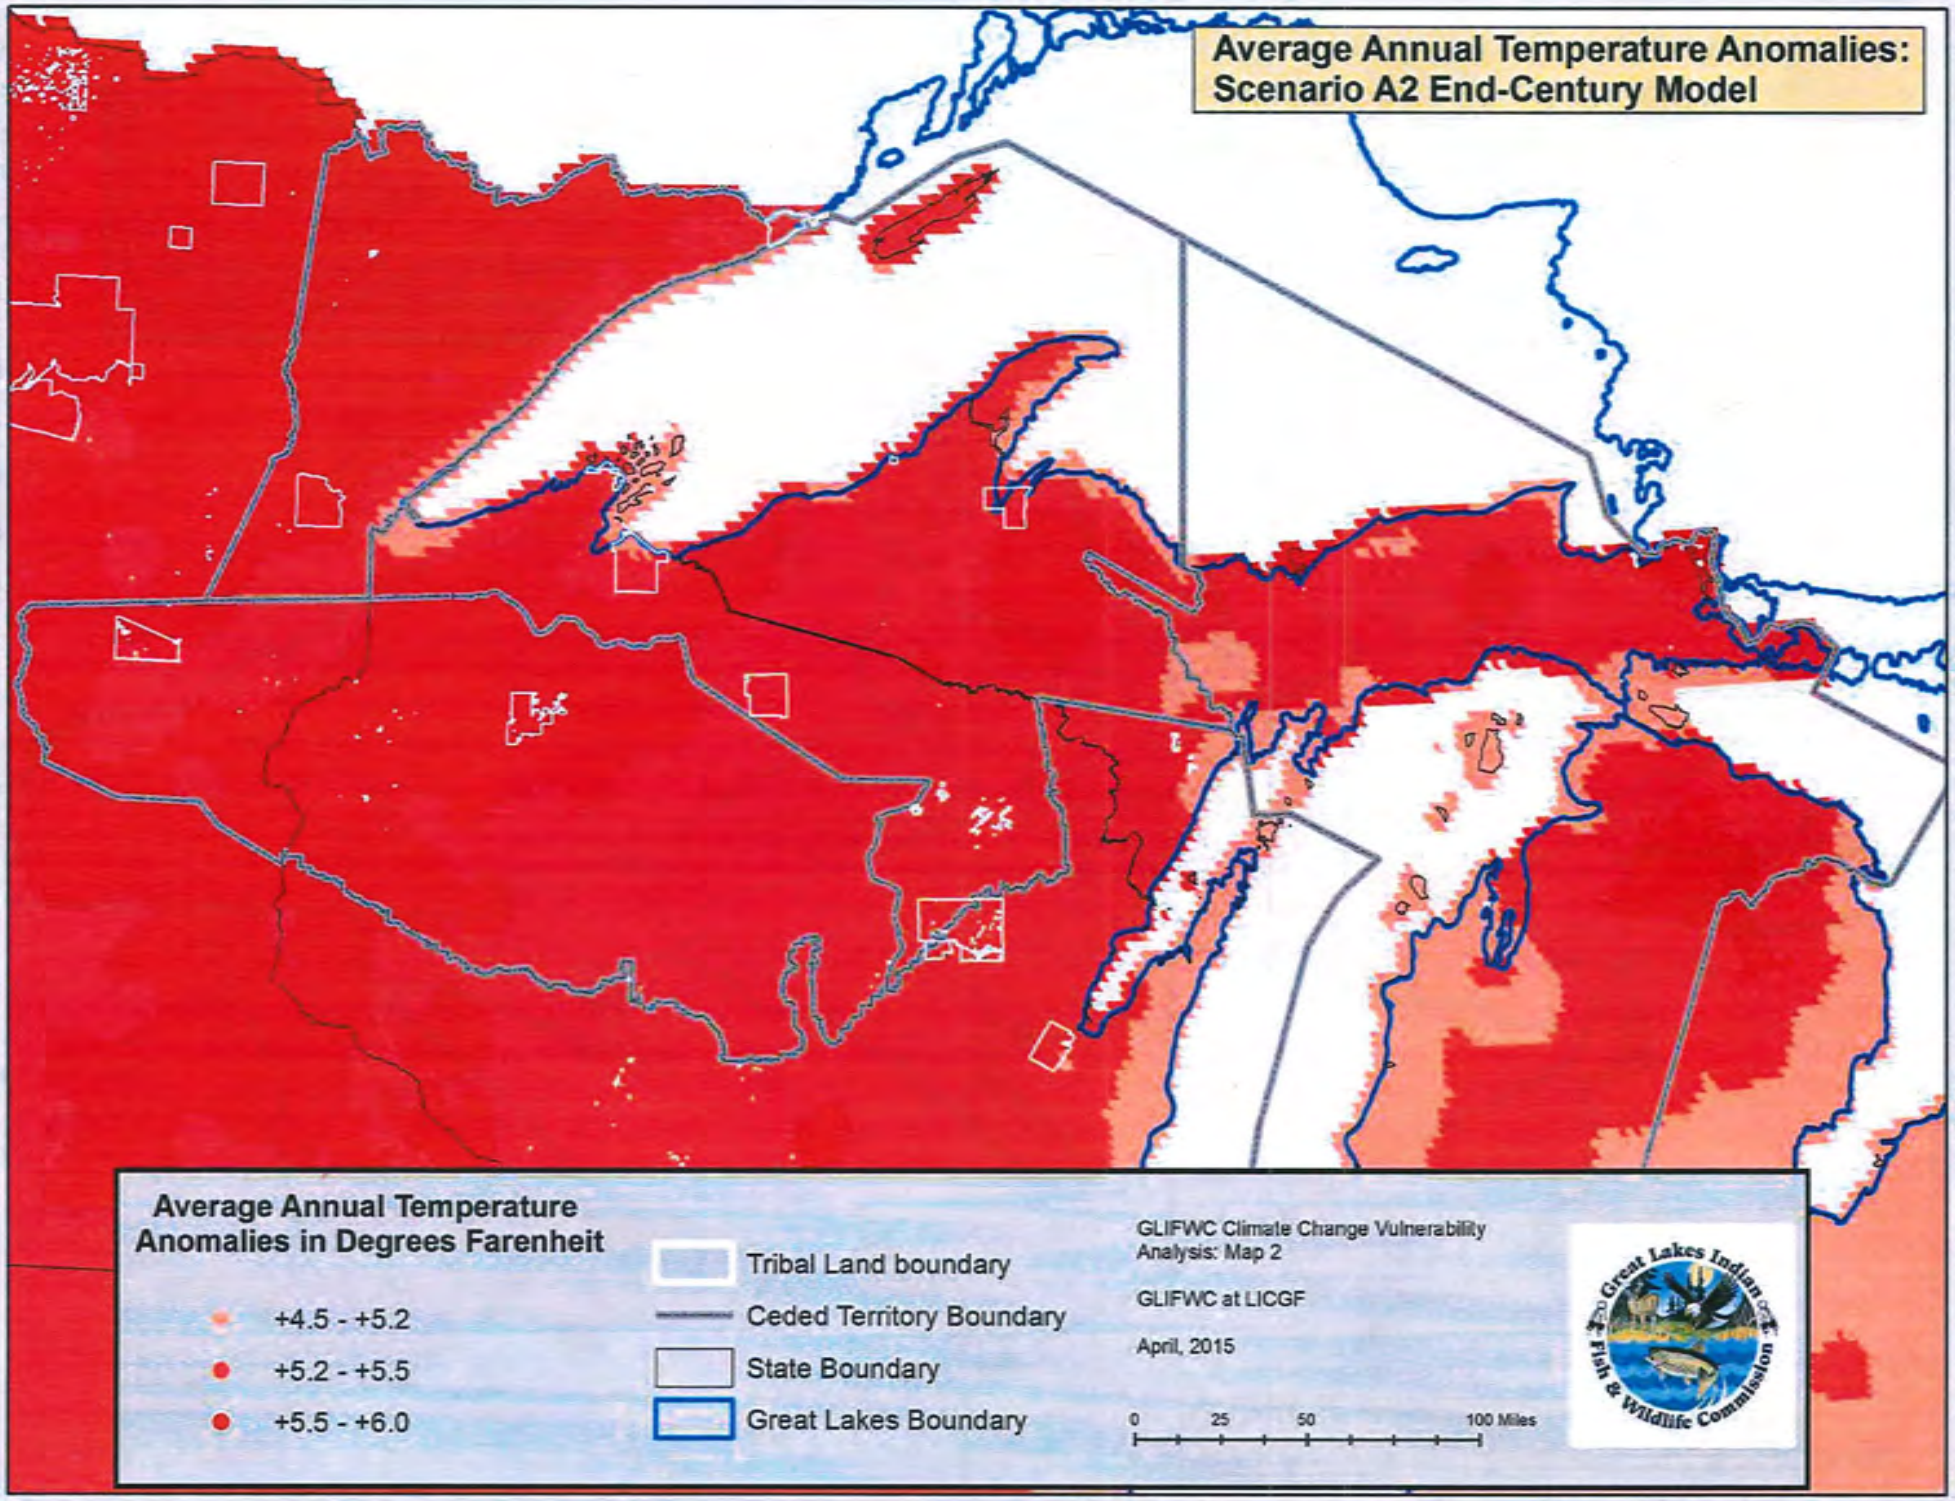
Sugar maple is an important species for tribal members and is found throughout the Ceded Territory (Map 37). Warmer years can mean the sugar maple -tapping season can get shorter and shorter. Warmer weather can also lead to problems with pests such as the Asian longhorn beetle. An Environmental Protection Agency Climate Action Report from 2002 notes that "climate change is likely to cause long-term shifts in forest species, such as sugar maples moving north out of the Ceded Territories." This can mean that the migration of sugar maple northwards may be unavoidable and ultimately threaten this aspect of Ojibwe sustenance living.

Sugar maple is expected to decline in the ceded territories by between 38 and 69 percent depending on the emission scenario (Maps 38 and 39). It is not expected to be completely eliminated from the CT but this species is vulnerable throughout the ceded territories.

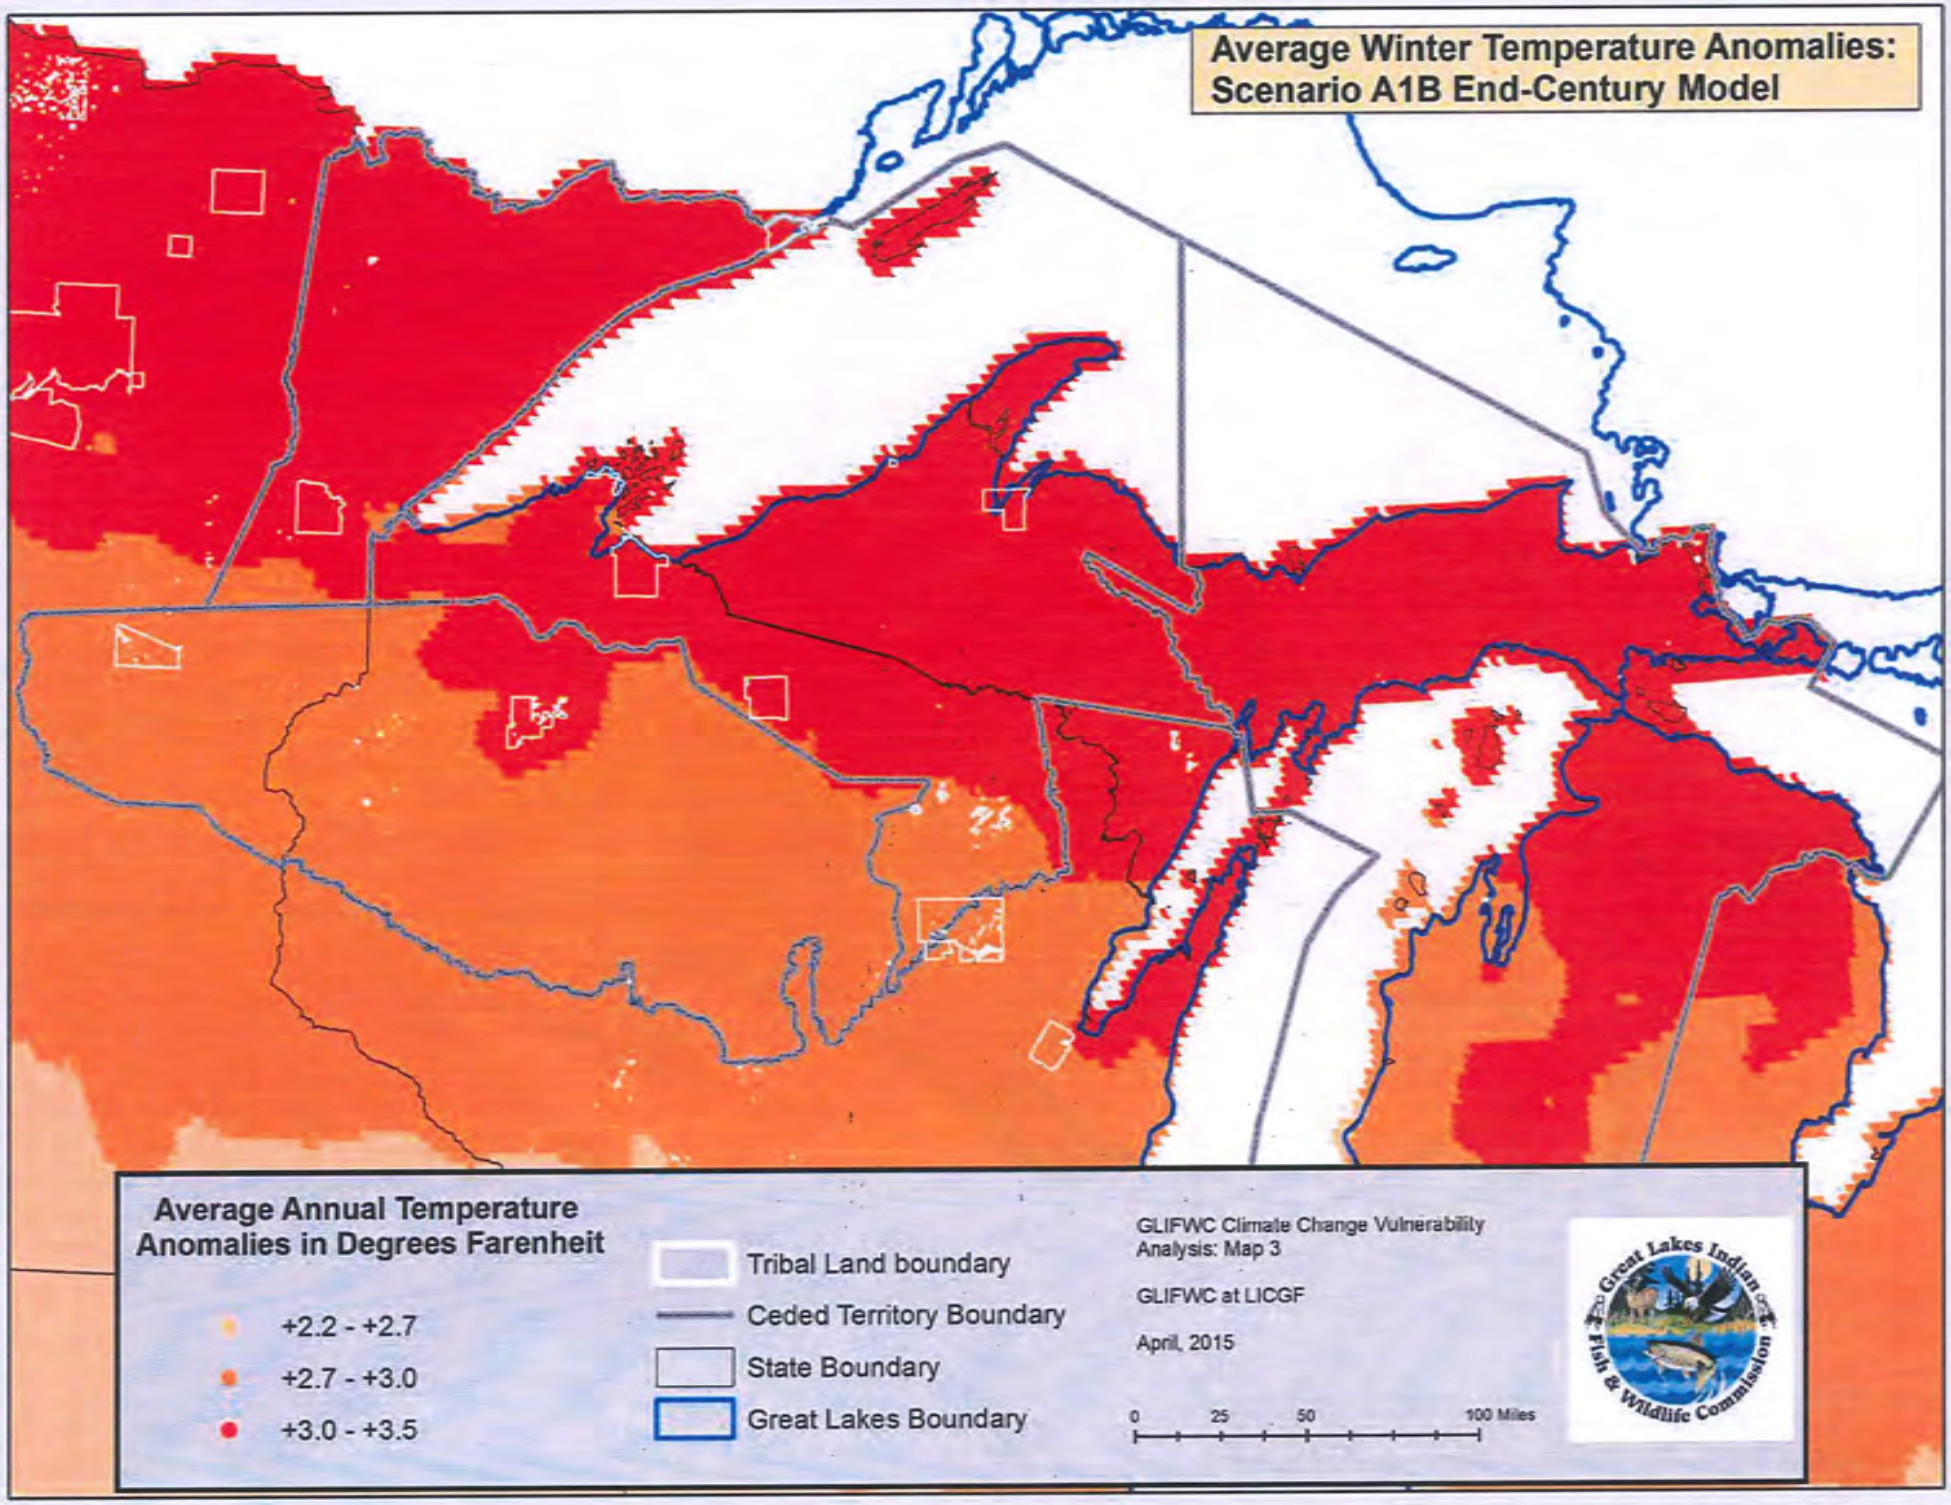
Giizhik (Northern White Cedar)



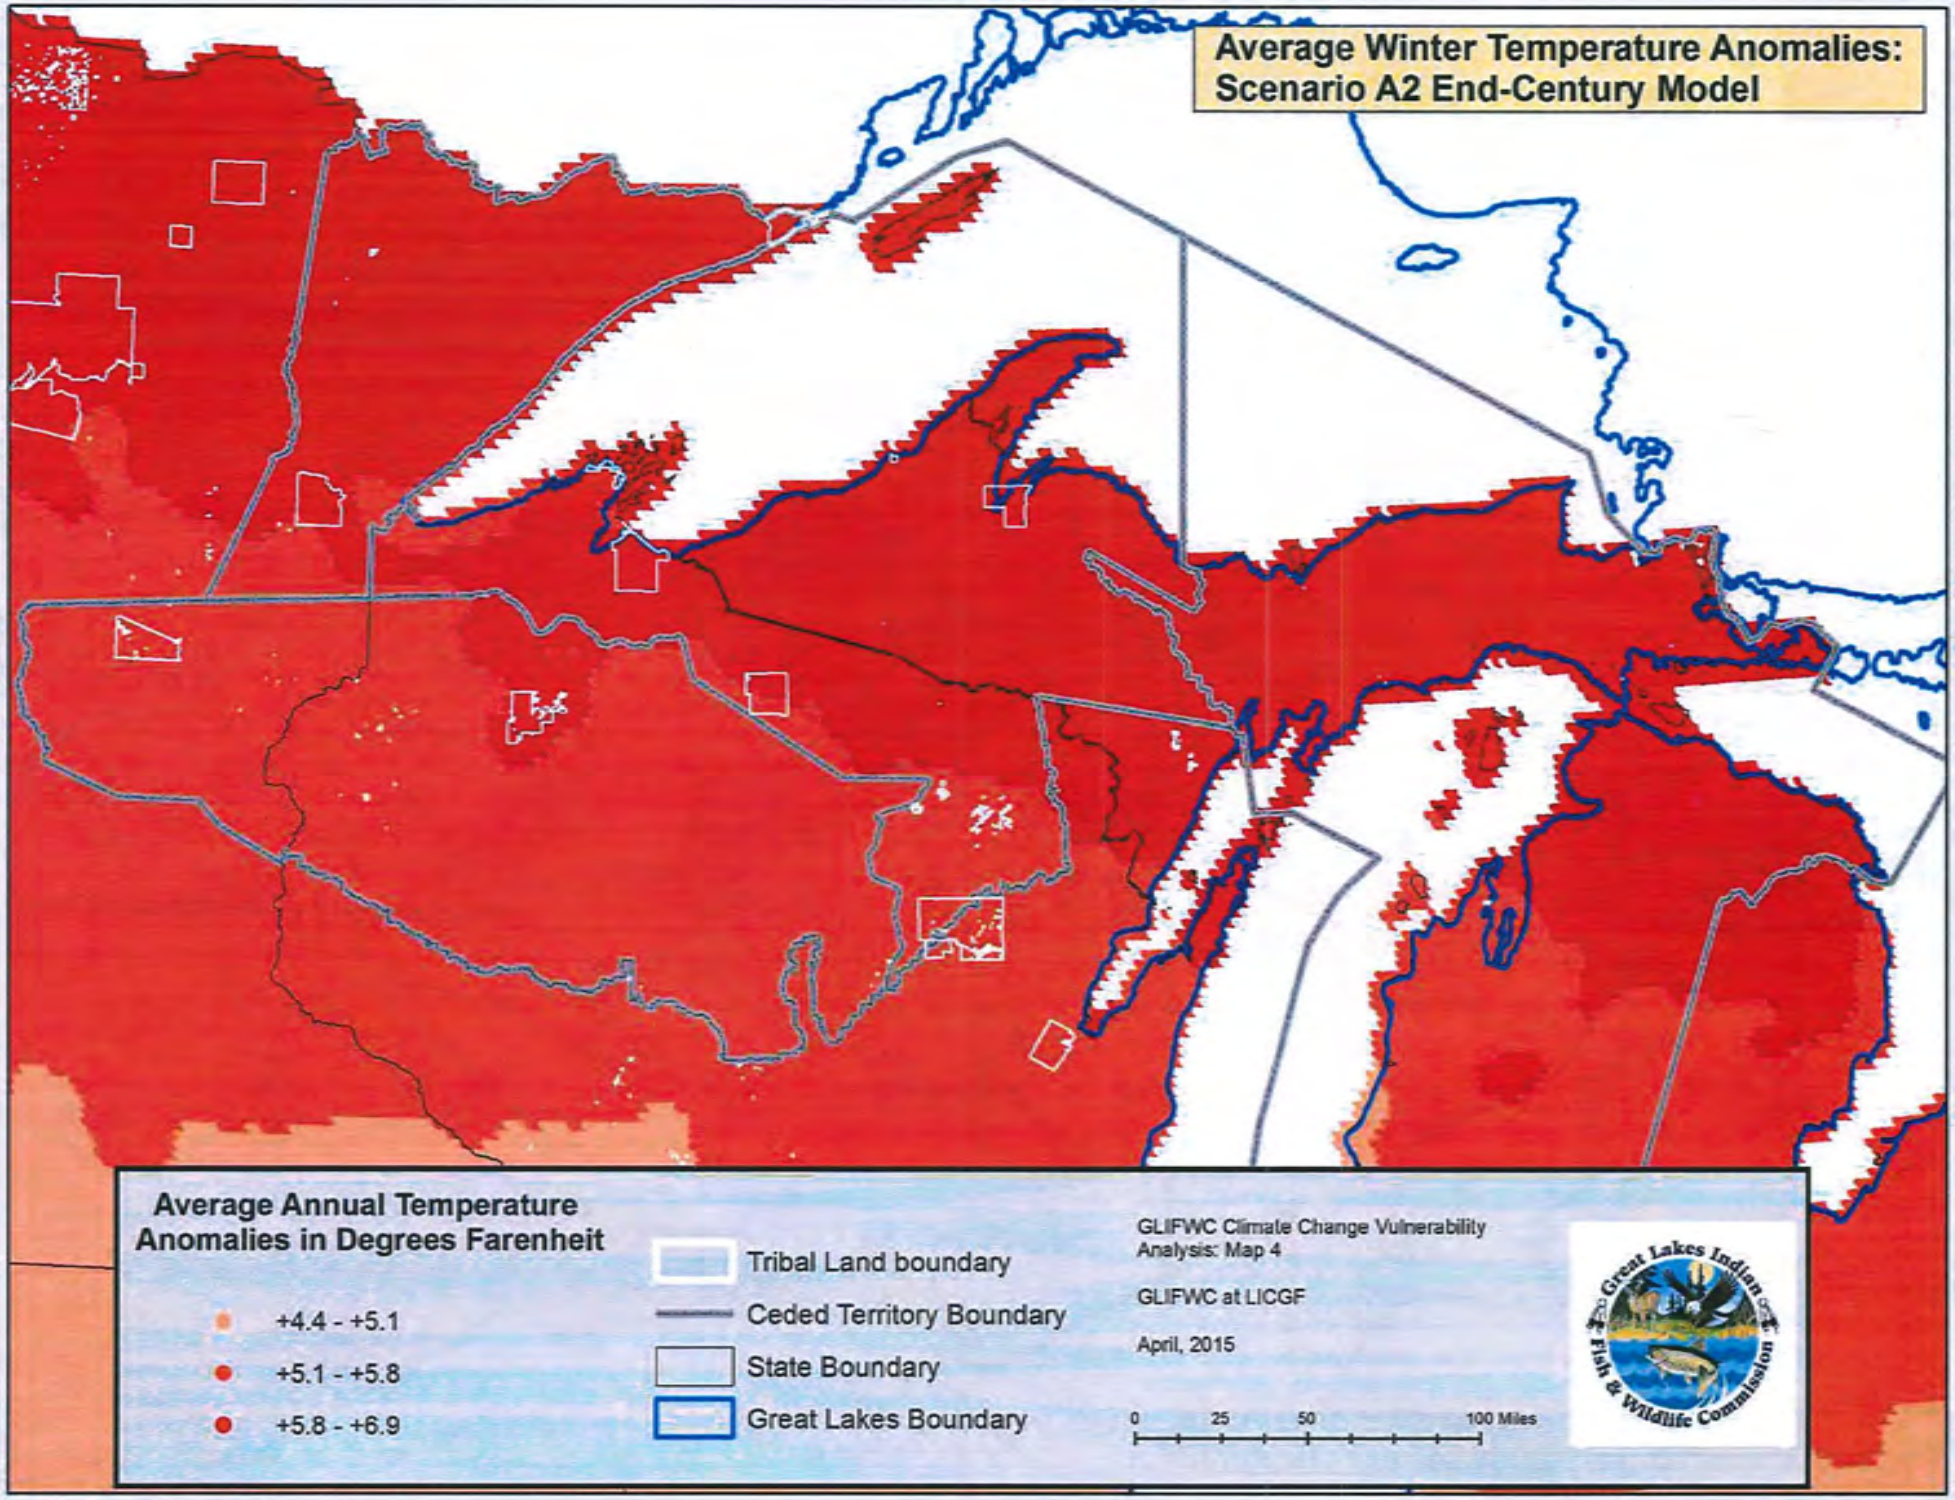
The current range encompasses the ceded territories but ends at the southernmost boundary, leaving it susceptible to northward migration, potentially eventually out of the ceded territories. In this area the warmer climates and longer growing seasons can have a "cumulative negative impact of all drivers of change. Storms, fires, invasive insects, and unsuitable climate will remove mature forests from the landscape, increasing deer populations will prevent reproduction of several species that would otherwise be resistant to the impacts of a warmer climate, including white pine, northern red oak, yellow birch, and northern white cedar".



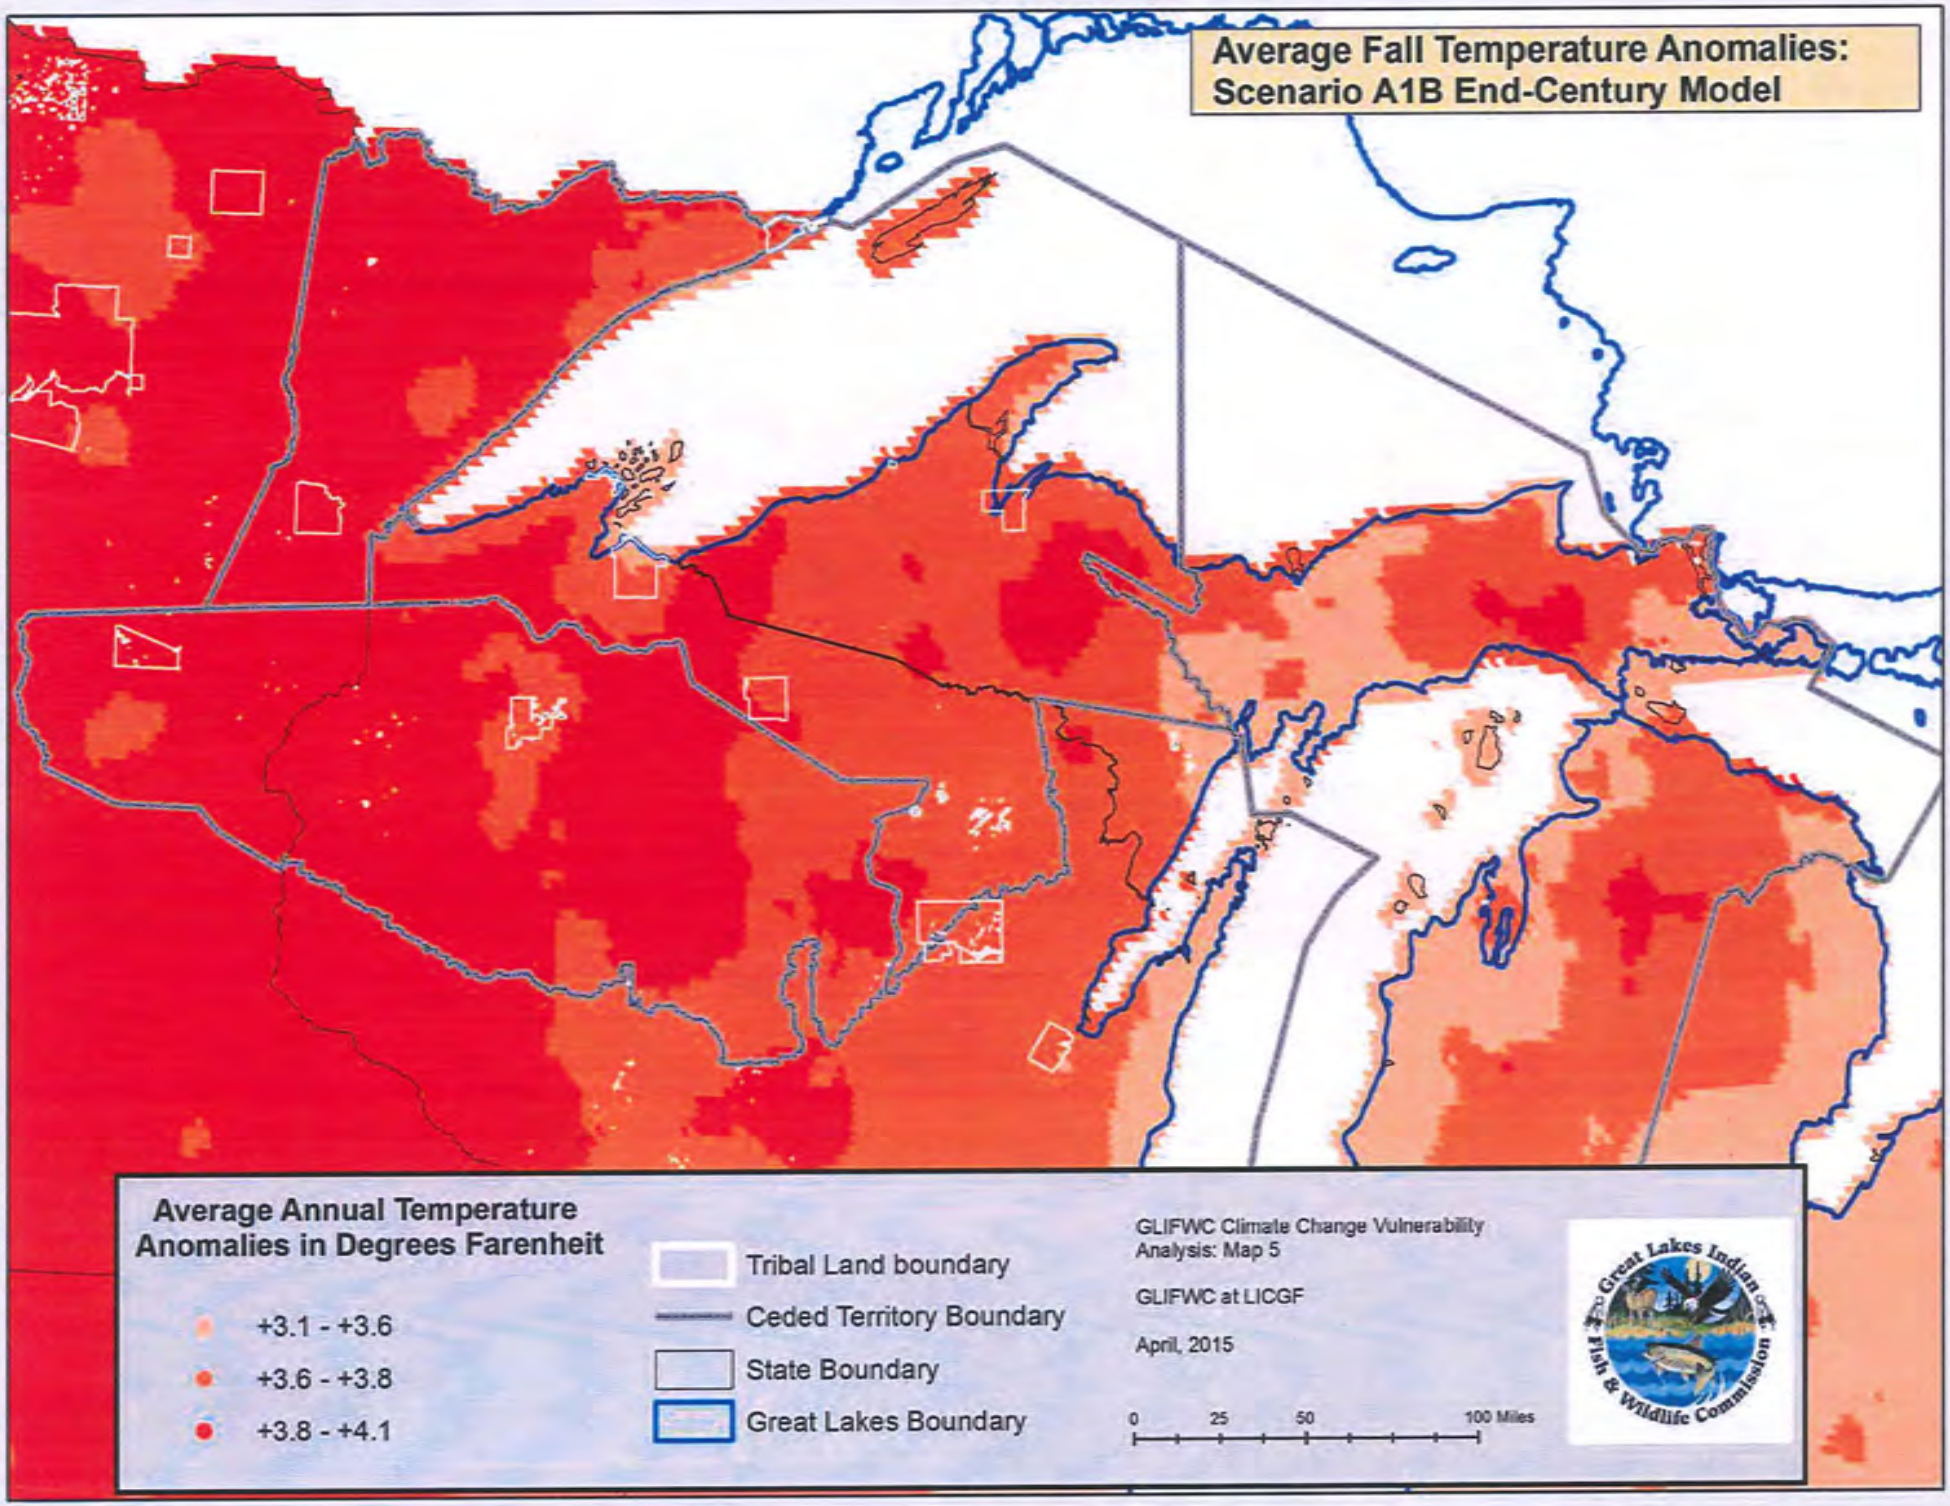
Discussion on Invasive Species



Invasive species are a non-climate stressor impacting habitats and species in the ceded territory. For example, emerald ash borer will have impacts on ash trees before the mid- and late century timeframes used in this assessment. Invasive species could create a positive feedback loop in which impacts from existing invasive species are expected to continue as climates change, and native habitats that have been degraded by invasive species become more vulnerable as climate changes. Future climates may then increase the likelihood of new infestations. For example, currently, the gypsy moth and asian carp cannot easily colonize areas of the ceded territory because they are limited by air and water temperatures. As both of these air and water temperatures rise, they may be able to invade areas farther north. This vulnerability assessment does not address invasive species in detail and additional research is needed to thoroughly assess each species and determine the potential impacts it may have on ecosystems throughout the Ceded Territories as climate change progresses.



Acknowledgements



Downscaled climate change data were developed by University of Wisconsin-Madison researchers through the Wisconsin Initiative on Climate Change Impacts. Downscaled climate change data developed by the National Center for Atmospheric Research (NCAR) was also used to provide context to WICCI data. The biologic information (e.g. species range, habitat descriptions, etc) are based on the expertise of the GLIFWC wildlife section biologists.

Annotated Bibliography

Lake Superior Fish

Lake Whitefish: Adikameg

1. Bronte, C.R., Ebener M.P., Schreiner D.R., DeVault D.S., Petzold M.M., Jensen D.A., Richards C., and Lozano S.J. (2003). Fish Community Change in Lake Superior, 1970-2000. *Canadian Journal of Fisheries and Aquatic Sciences,* 60(12), 1552–1574. Available at http://www.fws.gov/midwest/fisheries/scientific-pubs/p-2003-2.pdf

Summary: The Fish Community Change in Lake Superior discusses the changes in Lake Superior's fish communities from 1970 – 2000. In specific it touches on habitat degradation, contaminants, effects of climate warming, phosphorus loading, intentional and unintentional species introductions, as well as other topics. Habitat protection and enhancement to prevent additional damaging effects is needed to further restoration.

Specific pages to note: Pg. 1554: Climate warming is projected to increase thermal habitat; would be for Lake Trout, Lake Whitefish, Northern Pike, where non-indigenous species would benefit. This article focuses on fish species recovery.

2. Great Lakes Area National Park Service U.S. Department of the Interior. 2007. Climate Change: Dying Birch trees, minimal snowpack, and ice-free lakes are just some Impacts of Midwest Warming. Available at http://www.nps.gov/apis/naturescience/upload/2007%20MWR%20Climate%20Change%20Site%20Bulletin%20-%20Great%20Lakes%20FINAL.pdf

Summary: This article, Dying Birch Trees, Minimal Snowpack, and Ice-Free Lakes Are Just Some Impacts of Midwest Warming discusses climate change effects in the Midwest Region. It touches on the science reports by the U.S. Global Change Research Program as well as others and how they show that this is due to greenhouse gases produced by human activities. In specific the article has sections on Temperature and Precipitation, The Ecological Effects, New Faces in New Places, and Recreation, Health and Safety.

Specific pages to note: * Cool tree species are projected to lose habitat in the U.S. Sugar Maple and Paper Birch are expected to shift towards Canada. For the Apostle Island Lakeshore and Michigan Upper peninsula Paper Birch may lose all habitats. *Coldwater fish such as Trout will decrease in abundance. Whitefish spawning areas will be disturbed and Native fish will be threatened.

3. Kling, G.W., K. Hayhoe, L.B. Johnson, J.J. Magnuson, S. Polasky, S.K. Robinson, B.J. Shuter, M.M. Wander, D.J. Wuebbles, and D.R. Zak. 2003. Confronting Climate Change in the Great Lakes Region. A Report of the Union of Concerned Scientists and the Ecological Society of America. Available at

http://www.ucsusa.org/assets/documents/global_warming/greatlakes_final.pdf

Summary: Confronting Climate Change in the Great Lakes Region is a report of The Union of Concerned Scientists and The Ecological Society of America. This report explains that growing evidence suggests that climate change is already affecting the Great Lakes Region: winters are shorter, average temperatures are warmer, lake ice cover is decreasing, and heavy rainstorms are more common. The potential consequences from climate change for the Great Lakes Region are confronted for the economic as well as the environmental impacts.

Specific pages to note: **Pg. 2:** Whitefish reproduction could be threatened with the loss of winter ice [Coldwater fish (Lake Trout, Whitefish, Herring) and Coolwater fish (Northern Pike, Walleye) are likely to decline in abundance]. **Pg. 54-55**: If warmwater fish species expand and increase in number in Lake Superior, this could lead to the extirpation (local extinction) of native minnows. This could have negative impacts on Lake Trout and other Native predators. "Climate warming will greatly reduce the amount of thermally suitable habitat for Lake Trout in many inland lakes." **Pg. 60:** Moose could be harmed by warming: increase in deer populations could carry disease that will stress the moose population.

References Cited to Consider:

4. National Wildlife Federation. 2010. Improving the Odds: Using Climate-Readiness Planning to Reduce the Impacts of Climate Change on the Great Lakes Ecosystem. Available at http://www.nwf.org/News-and-Magazines/Media-Center/News-by-Topic/Global-Warming/2010/10-29-10-Great-Lakes-Adaptation-Report.aspx.

Summary: Improving the Odds was created by the National Wildlife Federation to bring awareness to Climate Change and to reduce the impacts of Climate Change. The report describes and analyzes climate-readiness initiatives in the Great Lakes Region. There are specifically looking at restoration practices that reduce climate impacts, implementing climate ready strategies and others. This is crucial to protect our natural resources, infrastructures, public health, as well as fresh water.

Specific pages to note: **Pg. 31:** It is expected that the Pine Marten will find no suitable habitat in Wisconsin. **Pg. 40:** Increased temperature of Lake Superior would benefit Sea Lamprey. This in turn will negatively affect fish species. Sea Lamprey feed on fish and warmer waters would allow for bigger growing Sea Lamprey. This will negatively affect Lake Trout, Herring, Whitefish as well as other species.

5. Sousounis, P.J. and J.M. Bisanz, eds. 2000. Preparing for a Changing Climate: The Potential Consequences of Climate Variability and Change. A Summary by the Great Lakes Regional
Assessment Group. U.S. Global Change Research Program. Available at http://www.geo.msu.edu/glra/PDF_files/GLRA_report.pdf.

Summary: Preparing for a Changing Climate was for the U.S. Global Change Research Program as an investment in science for the Nation's future. This report covers the potential consequences of climate variability and change. Climate change may bring negative affects to water resources, ecology, coastlines, human health, and others. They discuss the Great Lakes region and the impacts that are found in stream flow, aquatic and terrestrial ecosystems,

agriculture, and quality of life.

Specific pages to note: **Pg. 45**: Lake Trout would either potentially increase in size due to global warming (If their prey also increases in size) but would decrease in size if their prey simply stays the same size. **Pg. 92:** Less ice coverage may cause a fast decline of Whitefish; there would be a growing number of unprotected spawning areas.

Lake Trout: Namegos

1. Betz, C.R., Asplund T., and Hurley J. (2010). Water Resources Working Group Report. *Wisconsin Initiative on Climate Change Impacts.* Available at

http://www.wicci.wisc.edu/report/Water-Resources.pdf.

Summary: The Wisconsin Initiative on Climate Change Impacts discusses Wisconsin's changing climate and the impact this has on its water resources. Water Resources can indicate climate change at 'various temporal and spatial scales.' While climate change will affect Wisconsin differently in each geographic region, it is projected that all water resources will be affected in both quantity and quality.

Specific pages to note: **pg. VI**: Increased temperature could make coolwater and coldwater fish to no longer dominate some of Wisconsin's streams. Trout habitats will also be affected. **Pg. 33-35:** If rainfall is to increase, this will result in increased sediment and nutrient loads (from surrounding land and streams). This increase in sediment and nutrient loads could negatively impact the walleye population (who rely on sight to feed). There is the potential for warmwater fish to increase in abundances with coldwater species (such as Lake Trout) shifting farther north in search of cooler waters.

3. Casselman, J.M. 2002. Effects of temperature, global extremes, and climate change on year-class production of warmwater, coolwater, and coldwater fishes in the Great Lakes basin. Am. Fish. Soc. Symp. 31: 39–60. Available at ftp://142.36.245.139/.virtual/slk6ftp/pub/outgoing/requests/lage_analysis/CD1/Selected%20Age-Growth%20Publications/Climate%20and%20year-class%20production%20of%20fish,%20AFS%20Symposium,%20C.pdf

Summary: The Effects of Temperature, Global Extremes, and Climate Change on Year-Class Production of Warmwater, Coolwater, and Coldwater fishes in the Great Lakes Basin discuss the impacts of global warming on fisheries. For this they explain the effects of temperature change on fish. Global warming will substantially increase the year-class strength of warmwater species. It will also significantly impact the year-class strength and structure of fish communities in the Great Lakes Basin. Notably decreasing amounts of coldwater and coolwater fish species and increasing warrmwater fish species.

Specific pages to note: **Pg. 51:** Increased water temperature could have affected Northern Pike negatively; decreasing their year-class strength. **Pg. 52:** For Lake Trout, temperature increase would affect their spawning success. If the water temperature increases, their successful spawning survival would drastically decrease. *Water temperature increase would alter the food web and prey base. *Increase of water temperature would positively affect warmwater fish.

4. Great Lakes Area National Park Service U.S. Department of the Interior. 2007. Climate Change: Dying Birch trees, minimal snowpack, and ice-free lakes are just

some Impacts of Midwest Warming. Available at http://www.nps.gov/apis/naturescience/upload/2007%20MWR%20Climate%20Change%20Site%20Bulletin%20-%20Great%20Lakes%20FINAL.pdf

Summary: This article, Dying Birch Trees, Minimal Snowpack, and Ice-Free Lakes Are Just Some Impacts of Midwest Warming discusses climate change effects in the Midwest Region. It touches on the science reports by the U.S. Global Change Research Program as well as others and how they show that this is due to greenhouse gases produced by human activities. In specific the article has sections on Temperature and Precipitation, The Ecological Effects, New Faces in New Places, and Recreation, Health and Safety.

Specific pages to note: * Cool tree species are projected to lose habitat in the U.S. Sugar Maple and Paper Birch are expected to shift towards Canada. For the Apostle Island Lakeshore and Michigan Upper peninsula Paper Birch may lose all habitats. *Coldwater fish such as Trout will decrease in abundance. Whitefish spawning areas will be disturbed and Native fish will be threatened.

5. International Joint Commission (IJC). 2003. Climate Change and Water Quality in the Great Lakes Basin. Available at http://www.ijc.org/rel/pdf/climate_change_2003.pdf.

Summary: Climate Change and Water Quality in the Great Lakes Basin is a report of the Great Lakes Water Quality Board to the International Joint Commission. It discusses how our climate has been changing and will continue to change in the future. Investigations on climate change were undertaken. In the full report it is broken into the Water Quality Board's Advice to the International Joint Commission, Climate Change and Water Quality in the Great Lakes Region – Risks, Opportunities and Responses, Summary of the Climate Change Workshop, and Cross Boarder Tools and Strategies.

Specific pages to note: **Pg. 52:** Lake warming may shorten breeding windows for fish. This could affect both Lake Trout and Northern Pike. These fish species as well as coldwater fish species could potentially lose their habitat area.

A Report of the Union of Concerned Scientists and the Ecological Society of America. Available at http://www.ucsusa.org/assets/documents/global_warming/greatlakes_final.pdf

Summary: Confronting Climate Change in the Great Lakes Region is a report of The Union of Concerned Scientists and The Ecological Society of America. This report explains that growing evidence suggests that climate change is already affecting the Great Lakes Region: winters are shorter, average temperatures are warmer, lake ice cover is decreasing, and heavy rainstorms are more common. The potential consequences from climate change for the Great Lakes Region are confronted for the economic as well as the environmental impacts.

Specific pages to note: **Pg. 2:** Whitefish reproduction could be threatened with the loss of winter ice [Coldwater fish (Lake Trout, Whitefish, Herring) and Coolwater fish (Northern Pike, Walleye) are likely to decline in abundance]. **Pg. 54-55**: If warmwater fish species expand and increase in number in Lake Superior, this could lead to the extirpation (local extinction) of native minnows. This could have negative impacts on Lake Trout and other Native predators.

"Climate warming will greatly reduce the amount of thermally suitable habitat for Lake Trout in many inland lakes." **Pg. 60:** Moose could be harmed by warming: increase in deer populations could carry disease that will stress the moose population.

7. National Wildlife Federation. 2010. Improving the Odds: Using Climate-Readiness Planning to Reduce the Impacts of Climate Change on the Great Lakes Ecosystem. Available at http://www.nwf.org/News-and-Magazines/Media-Center/News-by-Topic/Global-Warming/2010/10-29-10-Great-Lakes-Adaptation-Report.aspx.

Summary: Improving the Odds was created by the National Wildlife Federation to bring awareness to Climate Change and to reduce the impacts of Climate Change. The report describes and analyzes climate-readiness initiatives in the Great Lakes Region. There are specifically looking at restoration practices that reduce climate impacts, implementing climate ready strategies and others. This is crucial to protect our natural resources, infrastructures, public health, as well as fresh water.

Specific pages to note: **Pg. 31:** It is expected that the Pine Marten will find no suitable habitat in Wisconsin. **Pg. 40:** Increased temperature of Lake Superior would benefit Sea Lamprey. This in turn will negatively affect fish species. Sea Lamprey feed on fish and warmer waters would

allow for bigger growing Sea Lamprey. This will negatively affect Lake Trout, Herring, Whitefish as well as other species.

U.S. Global Change Research Program. Available at http://www.geo.msu.edu/glra/PDF_files/GLRA_report.pdf.

Summary: Preparing for a Changing Climate was for the U.S. Global Change Research Program as an investment in science for the Nation's future. This report covers the potential consequences of climate variability and change. Climate change may bring negative affects to water resources, ecology, coastlines, human health, and others. They discuss the Great Lakes region and the impacts that are found in stream flow, aquatic and terrestrial ecosystems, agriculture, and quality of life.

Specific pages to note: **Pg. 45**: Lake Trout would either potentially increase in size due to global warming (If their prey also increases in size) but would decrease in size if their prey simply stays the same size. **Pg. 92:** Less ice coverage may cause a fast decline of Whitefish; there would be a growing number of unprotected spawning areas.

In land Fish

Walleye: Ogaa

1. Betz, C.R., Asplund T., and Hurley J. (2010). Water Resources Working Group Report. *Wisconsin Initiative on Climate Change Impacts.* Available at http://www.wicci.wisc.edu/report/Water-Resources.pdf.

Summary: The Wisconsin Initiative on Climate Change Impacts discusses Wisconsin's changing climate and the impact this has on its water resources. Water Resources can indicate climate change at 'various temporal and spatial scales.' While climate change will affect Wisconsin differently in each geographic region, it is projected that all water resources will be affected in both quantity and quality.

Specific pages to note: **pg. VI**: Increased temperature could make coolwater and coldwater fish to no longer dominate some of Wisconsin's streams. Trout habitats will also be affected. **Pg. 33-35:** If rainfall is to increase, this will result in increased sediment and nutrient loads (from surrounding land and streams). This increase in sediment and nutrient loads could negatively impact the walleye population (who rely on sight to feed). There is the potential for warmwater fish to increase in abundances with coldwater species (such as Lake Trout) shifting farther north in search of cooler waters.

Fish Community Change in Lake Superior, 1970-2000. *Canadian Journal of Fisheries and Aquatic Sciences,* 60(12), 1552–1574. Available at http://www.fws.gov/midwest/fisheries/scientific-pubs/p-2003-2.pdf

Summary: The Fish Community Change in Lake Superior discusses the changes in Lake Superior's fish communities from 1970 – 2000. In specific it touches on habitat degradation, contaminants, effects of climate warming, phosphorus loading, intentional and unintentional species introductions, as well as other topics. Habitat protection and enhancement to prevent additional damaging effects is needed to further restoration.

Specific pages to note: **Pg. 1554:** Climate warming is projected to increase thermal habitat; would be for Lake Trout, Lake Whitefish, Northern Pike, where non-indigenous species would benefit. This article focuses on fish species recovery.

Symp. 31: 39–60. Available at ftp://142.36.245.139/.virtual/slk6ftp/pub/outgoing/requests/lage_analysis/CD1/Selected%20Age-Growth%20Publications/Climate%20and%20year-class%20production%20of%20fish,%20AFS%20Symposium,%20C.pdf

Summary: The Effects of Temperature, Global Extremes, and Climate Change on Year-Class Production of Warmwater, Coolwater, and Coldwater fishes in the Great Lakes Basin discuss the impacts of global warming on fisheries. For this they explain the effects of temperature change on fish. Global warming will substantially increase the year-class strength of warmwater species. It will also significantly impact the year-class strength and structure of fish communities in the Great Lakes Basin. Notably decreasing amounts of coldwater and coolwater fish species and increasing warrmwater fish species.

Specific pages to note: **Pg. 51:** Increased water temperature could have affected Northern Pike negatively; decreasing their year-class strength. **Pg. 52:** For Lake Trout, temperature increase would affect their spawning success. If the water temperature increases, their successful

spawning survival would drastically decrease. *Water temperature increase would alter the food web and prey base. *Increase of water temperature would positively affect warmwater fish.

Summary: Climate Change and Water Quality in the Great Lakes Basin is a report of the Great Lakes Water Quality Board to the International Joint Commission. It discusses how our climate has been changing and will continue to change in the future. Investigations on climate change were undertaken. In the full report it is broken into the Water Quality Board's Advice to the International Joint Commission, Climate Change and Water Quality in the Great Lakes Region – Risks, Opportunities and Responses, Summary of the Climate Change Workshop, and Cross Boarder Tools and Strategies.

Specific pages to note: **Pg. 52:** Lake warming may shorten breeding windows for fish. This could affect both Lake Trout and Northern Pike. These fish species as well as coldwater fish species could potentially lose their habitat area.

A Report of the Union of Concerned Scientists and the Ecological Society of America. Available at http://www.ucsusa.org/assets/documents/global_warming/greatlakes_final.pdf

Summary: Confronting Climate Change in the Great Lakes Region is a report of The Union of Concerned Scientists and The Ecological Society of America. This report explains that growing evidence suggests that climate change is already affecting the Great Lakes Region: winters are shorter, average temperatures are warmer, lake ice cover is decreasing, and heavy rainstorms

are more common. The potential consequences from climate change for the Great Lakes Region are confronted for the economic as well as the environmental impacts.

Specific pages to note: **Pg. 2:** Whitefish reproduction could be threatened with the loss of winter ice [Coldwater fish (Lake Trout, Whitefish, Herring) and Coolwater fish (Northern Pike, Walleye) are likely to decline in abundance]. **Pg. 54-55**: If warmwater fish species expand and increase in number in Lake Superior, this could lead to the extirpation (local extinction) of native minnows. This could have negative impacts on Lake Trout and other Native predators. "Climate warming will greatly reduce the amount of thermally suitable habitat for Lake Trout in many inland lakes." **Pg. 60:** Moose could be harmed by warming: increase in deer populations could carry disease that will stress the moose population.

Wildlife

Pine Marten (American Marten): Waabizheshi

1. National Wildlife Federation. 2010. Improving the Odds: Using Climate-Readiness Planning to Reduce the Impacts of Climate Change on the Great Lakes Ecosystem. Available at http://www.nwf.org/News-and-Magazines/Media-Center/News-by-

Topic/Global-Warming/2010/10-29-10-Great-Lakes-Adaptation-Report.aspx.

Summary: Improving the Odds was created by the National Wildlife Federation to bring awareness to Climate Change and to reduce the impacts of Climate Change. The report describes and analyzes climate-readiness initiatives in the Great Lakes Region. There are specifically looking at restoration practices that reduce climate impacts, implementing climate ready strategies and others. This is crucial to protect our natural resources, infrastructures, public health, as well as fresh water.

Specific pages to note: **Pg. 31:** It is expected that the Pine Marten will find no suitable habitat in Wisconsin. **Pg. 40:** Increased temperature of Lake Superior would benefit Sea Lamprey. This in turn will negatively affect fish species. Sea Lamprey feed on fish and warmer waters would allow for bigger growing Sea Lamprey. This will negatively affect Lake Trout, Herring, Whitefish as well as other species.

2. Wisconsin Department of Natural Resources: Bureau of Endangered Resources. 2011. Management and Conservation Plan for American Martens in Wisconsin. Available at http://dnr.wi.gov/files/PDF/pubs/ER/ER0697.pdf

Summary: Management and Conservation Plan For American Martens In Wisconsin was created by the Wisconsin Department of Natural Resources as a plan to update the conservation status of the American Marten to ensure they remain a viable member in Wisconsin today and for generations to come. This plan provides background information on Martens including both the cultural significance and socio-economic importance of the Marten. It also provides past and current status of the Marten's life histories, habitats, and threats. It provides information on current research, management goals, and research needs.

Specific pages to note: **Pg. 20:** Climate change will decrease the amount of snowfall or snow pack. Martens need this snow to help them escape from predators. They will also lose their advantage over fishers and other competitors resulting from climate change or climate

warming.

3. Wisconsin Initiative on Climate Change Impacts. 2011. Wisconsin's Changing Climate: Impacts and Adaptation. Nelson Institute for Environmental Studies, University of Wisconsin- Madison and the Wisconsin Department of Natural Resources. Available at http://www.wicci.wisc.edu/publications.php

Summary: This report was created by the Wisconsin Initiative on Climate Change Impacts. It discusses Wisconsin's changing climate in which we now have a warmer, wetter Wisconsin climate. This change has affected precipitation, air temperatures, the quantity and quality of Wisconsin's water resources, natural habitats, agriculture, as well as others. This report is to provide information so that Wisconsin can adapt to the impacts of climate change and create strategies to adapt successfully to current and future climate change.

Specific pages to note: **Chapter 4:** The marten needs areas underneath the snow. Climate warming will lead to increasing in snow density. This will decrease the amount of thermal insulation which the Marten needs for survival. Climate warming will expose the Marten to the cold weather. Also Climate change will threaten the Marten's food source. Martens will also be threatened by more preditation; there will be fewer areas for the Marten to hide.

Fisher: Ojiig Martes pennanti

1. Olson, L. E., Sauder, J. D., Albrecht, N. M., Vinkey, R. S., Cushman, S. A., & Schwartz, M. K. (2014). Modeling the effects of dispersal and patch size on predicted fisher (Pekania [Martes] pennanti) distribution in the US Rocky Mountains. *Biological Conservation, 169*, 89-98.

Summary: Modeling the effects of dispersal and patch size on predicted fisher distribution in the US Rocky Mountains is an article discussing the impacts climate change will have on habitats. This article specifically looks at the fisher, an already threatened species. They specifically look at fishers located across western Montana and Northern Idaho.

Specific pages to note: **Pg. 93:**The variables that contribute the most to fisher habitat suitability are 25-20 m canopy height, montane riparian vegetation, topographic positions index and mean annual precipitation. 3.2: Fisher habitat is predicted to increase. Fisher habitat is also predicted to shift north. **Pg. 95:** Fishers were more likely to occur in areas with higher mean annual precipitation, mid-range minimum winter temperatures... across both models. **Pg. 97:** Fishers are predicted to expand under climate warming but if they cannot find suitable habitat to disperse in distance greater than 4km then they will likely decline over time.

2. McCamman J. (2010). Report to the California Fish and Game Commission: A Status Review of the Fisher (Martes pennanti) in California. State of California Natural Resources Agency Department of Fish and Game. Available at, https://nrm.dfg.ca.gov/FileHandler.ashx?DocumentID=27900

Summary: A status Review of the Fisher in California was created to report to the California Fish and Game Commission about the current status of the fisher. This report was designed to give background history on the Fisher and their habits, what is needed for their survival, their distribution and abundance, and potential threats to the Fisher. One threat indicated for the Fisher is the current and projected future climate change.

Specific pages to note: **Pg. 57-60:** Prey and den availability for the Fisher may change. Climate Change may exacerbate wildfires which would have negative impacts on Fishers. Stress caused by unideal temperature conditions may lead Fishers to become more susceptible to disease. Lack of deep snow may allow w the Fisher to inhabit areas otherwise not available (as long as wildfires do not destroy the areas making them unsuitable first).

3. Safford, H.D. 2006. Potential impacts of climate change to fisher habitat in California: a preliminary assessment. Unpublished report. U.S. Forest Service, Pacific Southwest Region, Vallejo, CA. Available at http://www.sierraforestlegacy.org/Resources/Conservation/SierraNevadaWildlife/PacificFisher/PF-Safford06.pdf

Summary: This unpublished article addresses the potential impacts that Climate Change could have on the Fisher. Findings indicate that fire is likely to become much more frequent which

would have negative impacts on the Fisher. Fires are likely to destroy many habitats needed by the Fisher for denning.

Specific pages to note: **Pg. 9:** Fishers will more than likely lose crucial denning habitat due to fire increases. However, Fishers may be enhanced by climate warming as long as precipitation levels stay about what they are currently.

2. Lankester, M.W. 2010. Understanding the Impact of Meningeal Worm, Parelaphostrongylus tenuis, on Moose Populations. Alces Vol. 46: 53-70.

Summary: Understanding the Impacts of Meningeal Worm on Moose Populations is an article that explores the declines in moose populations that have occurred during the past century. In general these decreases in moose population are associated with higher deer populations. This inverse relationship is caused by the Meningeal worm, a parasite that white-tailed deer carry and have shown deadly to moose population when stressed. Climate change causing warmer winters is a factor that has caused an increase in deer population in moose habitat.

Specific pages to note: **Pg. 54:** There is a seen inverse relationship between moose and deer density. Less severe winters allow for an increase of deer density that then transmits diseases to the moose populations. *With Climate warming the frequency of less-severe winters would increase. This would allow for an increase in deer density which would negatively affect moose

populations.

References Cited to Consider:

- *Lenarz, M. S., Nelson, M. E., Schrage, M. W., & Edwards, A. J. (2009). Temperature mediated moose survival in northeastern Minnesota. The Journal of Wildlife Management, 73(4), 503-510.*
- *Murray, D. L., Cox, E. W., Ballard, W. B., Whitlaw, H. A., Lenarz, M. S., Custer, T. W., ... & Fuller, T. K. (2006). Pathogens, nutritional deficiency, and climate influences on a declining moose population. Wildlife Monographs, 166(1), 1-30.*

3. Michigan Technical University. 2007. Global Warming Threatens Moose, Wolves. Michigan Tech News/Media, August 15, 2007. Available at http://www.admin.mtu.edu/urel/news/media_relations/592.

Summary: The article Global Warming Threatens Moose, Wolves discusses the fact that if moose and wolves go extinct it will because of humans that make climate change increase at a faster rate. Hot summers exacerbate moose ticks which combined with the heat are detrimental to moose populations. The hot summers and ticks make moose easy prey for wolves to kill. If moose continue to drop in population it will not only affect the moose themselves but wolf population as well.

Specific pages to note: *The heat threatens the Moose. Hot weather causes moose to forage less and rest more. If they forages less it will be less likely that they survive in the winter.

4. Minnesota Department of Natural Resources. 2011. Minnesota Moose Research and Management Plan. Available at http://www.dnr.state.mn.us/moose/index.html.

Summary: The Minnesota Moose Research and Management Plan which was created by the Minnesota Department of Natural Resources because the moose population in Minnesota is currently in decline. Their findings show that moose population decline is associated with increasing summer temperature. This report is recommendations to DNR to better understand what the moose populations need to reverse this decline.

Specific pages to note: **Pg. 30:** Research implies that climate warming is contributing to the high mortality rates of moose. Higher temperatures are contributing to stress on moose, which leave them vulnerable to disease, predators, parasites, etc. There is a link between moose populations and climate warming.

References Cited to Consider:

Plants

Wild Rice: Manoomin

1. Cuffe, S. 2014. Wild Rice and High Water: A Northern Harvest Under Threat. Briarpatch Magazine. Available at: http://briarpatchmagazine.com/articles/view/wild-rice-and-high-water

Summary: An article written to discuss Wild Rice and harvesters in Saskatchewan and Minnesota. Methods to try and control the wild rice while facing the effects of climate change. This article touches on the sensitivity wild rice has to environment change and that climate change can cause stress on the rice. Wild Rice is a traditionally important crop to the Anishinaabe and now there are domesticated hybrids of it, which also bring risks to the natural wild rice.

Specific Pages to Note: Wild rice is very susceptible to water change. If it gets too high at certain times of the year it will drown out the wild rice which, climate change could have an effect on. Strong winds, heavy rains, and hail can cause damage to wild rice crops. This plant also depends on a certain amount of natural water circulation, and is very particular of when, where, and how it grows.

2. Ojibwe Lifeway: Wild Rice Harvesting ("Dagwaagin" – Fall). Gikinoo'wizhiwe Onji Waaban (Guiding For Tomorrow) "G-WOW" Changing Climate, Changing Culture. Available at: http://www.g-wow.org/en-us/wildrice/default.aspx

Summary: Gikinoo'wizhiwe Onji Waaban is a website designed to look at Ojibwe lifeways and how they are affected by climate change. This specific one looks to understand wild rice, the importance of the crop to the Ojibwe people and climate related stressors that have been and

will affect these wild rice crops.

Specific Pages to Note: Climate Related issues: water level has dire consequences to wild rice; it can kill the plants with either too little or too much water. Intense rainfall can also drown wild rice plants or uproot them. Certain invasive species are out competing wild rice crops. Disease and insects that damage wild rice have been increasing noticeable with the warming climate.

3. Hoene, N. 2010. Climate Change, an Ojibwe Perspective. The Seiche. Minnesota Sea Grant, March 2010. Available at http://www.seagrant.umn.edu/newsletter/2010_03.html.

Summary: Climate Change, an Ojibwe Perspective is an article discussing different Tribal members and their observation on the effects of climate change. Wild Rice, Maple Sugar, Birch, Pine, and other elements used in the Ojibwe culture are discussed on how climate change will impact them.

Specific pages to note: **Maple Sugar:** Sap has been running sooner; with a warmer climate it could start to run, and then stop. **Wild Rice:** It cannot stand extreme water level changes. **Coldwater Fish:** They will not stay if the streams warm by even a few degrees. **Tree:** A warmer climate means the loss of Birch, and potentially Sugar Maple if there is an increase in forest fires.

4. Myers, J. 2014. Wild Rice Under the Microscope: Scientists Work Fast to Learn What Sulfate Does to Minnesota's Iconic Natural Food. Minnesota Department of Natural Resources. Available at: http://www.dnr.state.mn.us/volunteer/mayjun13/wild_rice.html

Summary: This is a study conducted by the University of Minnesota on wild rice, specifically on the impact sulfate has on wild rice. It is specifically meant to understand the relationship between sulfate and wild rice. It discusses what wild rice needs for growth and factors could affect its growth. One factor briefly mentioned is climate change.

Specific Pages to Note: If sulfate is placed in the lakes, wild rice will not immediately die; there is a whole ecosystem that has to react which happens over years. Climate warming, floods and droughts also cause problems for wild rice crops. There are seen decreases in the amount of wild rice crops that have been having rice in them.

5. Pember, Mary A. 2012. Climate Change Threatens the Ojibwe's Wild Rice Harvest. Indian Country Today Media Network. Available at: http://indiancountrytodaymedianetwork.com/2012/11/02/climate-change-threatens-ojibwes-wild-rice-harvest-143579

Summary: An article written for Indian Country Today Media Network first discussing the importance of Wild Rice to the Ojibwe stories, mentioning their migration story. It mentions how wild rice crops have seen a total loss in 2012. Finally it goes through how climate change is a factor relating to the decreased amounts of wild rice in the sloughs.

Specific Pages to Note: Wild rice, manoomin favor colder temperatures, climate warming could cause manoomin to shift farther north. It could also have caused higher rates of disease within the crops of manoomin.

6. Yeager, C. Where Food Grows on Water: Environmental and Human Threats to Wisconsin's Wild Rice. 2011. Circle of Blue. Available at: http://www.circleofblue.org/waternews/2011/world/where-food-grows-on-water-environmental-and-human-made-threats-to-wisconsins-wild-rice/

Summary: This article is written on Wisconsin's rice beds and the threats that they face from both humans and the environment. It discusses the various growing stages wild rice goes through. Examples of climate change harming wild rice being water levels in the Great Lakes, storms, and heavy rains. Lastly, the article touches on the importance of Wild Rice to the Anishinaabe with an interview from Joe Rose, Bad River Tribal Elder.

Specific Pages to Note: A warming climate could lead to lower water levels in the Great Lakes; this would have dire impacts on wild rice crops. Increased flooding or heavy rains caused from climate change could drown or uproot wild rice crops especially when it is in its floating leaf stage (a critical and fragile time in the growth cycle). There have been seen changes in wild rice beds caused by climate change in Wisconsin.

Trees

Sugar Maple: Ziinzibaakwadaatig

1. *Frumhoff, P.C.; McCarthy, J.J.; Melillo, J.M.; Moser, S.C.; Wuebbles, D.J. 2007. Confronting Climate Change in the U.S. Northeast: Science, Impacts and Solutions. Synthesis Report of the Northeast Climate Impacts Assessment (NECIA). Cambridge,*

MA: Union of Concerned Scientists. Available at: http://www.northeastclimateimpacts.org/pdf/confronting-climate-change-in-the-u-s-northeast.pdf

Summary: This report discusses the Northeast and how they experience huge climate diversity within a small area. This area has also experienced drastic climate change since 1970, with a warming rate of almost 0.5 degrees Fahrenheit per decade. With the experienced climate warming there have been seen changes in the environment. This report was created to understand past and future climate change, to understand the potential effects that climate change could bring about.

Specific pages to note: **Pg. 49 & 55:** Projections indicate that male habitat will shift northward under either climate change scenario. Southern species of trees eventually become their replacements in the Northeast. Climate change will also leave the maple tree more susceptible to disease, pests, drought, wildfire, and storm damage. **Pg. 55 & 58:** Sugar maple is expected to lose drastic amounts of suitable habitat. It could have the chance of surviving under climate warming but a warmer winter is expected disrupt the winter pattern sugar maples need for optimal syrup production. **Pg. 59:** With a projected decrease in Maples and the loss of their colorful changing leaves in the fall, tourism could suffer in the Northeast. **Pg. 74:** Maple Syrup has seen a shift in the time it usual is produced, which has caused a decline in the syrup industry. Global warming is one possibility as to why this shift has occurred, and is likely to keep occurring.

2. Great Lakes Area National Park Service U.S. Department of the Interior. 2007. Climate Change: Dying Birch trees, minimal snowpack, and ice-free lakes are just some Impacts of Midwest Warming. Available at http://www.nps.gov/apis/naturescience/upload/2007%20MWR%20Climate%20Change%20Site%20Bulletin%20-%20Great%20Lakes%20FINAL.pdf

Summary: This article, Dying Birch Trees, Minimal Snowpack, and Ice-Free Lakes Are Just Some Impacts of Midwest Warming discusses climate change effects in the Midwest Region. It touches on the science reports by the U.S. Global Change Research Program as well as others and how they show that this is due to greenhouse gases produced by human activities. In specific the article has sections on Temperature and Precipitation, The Ecological Effects, New Faces in New Places, and Recreation, Health and Safety.

Specific pages to note: * Cool tree species are projected to lose habitat in the U.S. Sugar Maple and Paper Birch are expected to shift towards Canada. For the Apostle Island Lakeshore and Michigan Upper peninsula Paper Birch may lose all habitats. *Coldwater fish such as Trout will decrease in abundance. Whitefish spawning areas will be disturbed and Native fish will be threatened.

3. Hoene, N. 2010. Climate Change, an Ojibwe Perspective. The Seiche. Minnesota Sea Grant, March 2010. Available at http://www.seagrant.umn.edu/newsletter/2010_03.html.

Summary: Climate Change, an Ojibwe Perspective is an article discussing different Tribal members and their observation on the effects of climate change. Wild Rice, Maple Sugar, Birch,

Pine, and other elements used in the Ojibwe culture are discussed on how climate change will impact them.

Specific pages to note: **Maple Sugar:** Sap has been running sooner; with a warmer climate it could start to run, and then stop. **Wild Rice:** It cannot stand extreme water level changes. **Coldwater Fish:** They will not stay if the streams warm by even a few degrees. **Tree:** A warmer climate means the loss of Birch, and potentially Sugar Maple if there is an increase in forest fires.

4. Ojibwe Lifeway: Maple Sugaring and Birch Bark Harvesting ("Ziigwan" – Spring). Gikinoo'wizhiwe Onji Waaban (Guiding for Tomorrow) "G-Wow" Changing Climate, Changing Culture. Available at: http://www.g-wow.org/en-us/maple_birch/default.aspx

Summary: Gikinoo'wizhiwe Onji Waaban is a website designed to look at Ojibwe lifeways and how they are affected by climate change. This specific one looks to understand both sugar maples and birch bark trees. It covers the specific cultural importance of these trees. As well as, includes impacts they face resulting from climate change and possible climate change stressors.

Specific Pages to Note: Climate warming will cause a decrease in suitable habitat for Sugar Maple. Climate warming could also have an impact on soil moisture which will inhibit Sugar Maple's effectiveness to receive water and nutrients. Climate change may also allow for an increase in disease and pests. Lastly, shorter winters may cause stress on the Sugar Maple and allow for greater vulnerability to pests. This in turn will cause a decrease in the Maple Sap production.

5. *Rustad, L., Campbell, J., Dukes, J.S., Huntington, T., Lambert, K.F., Mohan, J., Rodenhouse, N. Changing Climate, Changing Forests: The Impacts of Climate Change on Forests of the Northeastern United States and Eastern Canada. United States Department of Agriculture. 2012. Available at*: http://www.nrs.fs.fed.us/pubs/gtr/gtr_nrs99.pdf

Summary: This was created to study climate change and the effects it poses on forest ecosystems with the goal to provide important insights for forest science, management, and policy. Climate change is predicted to have dire effects on habitat locations of tree species. A decline in suitable habitats is expected with a change in abundance and distribution of wildlife.

Specific pages to note: **Pg. 13**: Tourism would be affected with a shift from Sugar maples to Oaks. **Pg. 17 & 18:** Table 2. Shows that Sugar maple is expected to lose suitable habitat. Maple will lose habitat in either climate change scenario. **Pg. 20:** Sugar maple could decline based on prolonged thaw-freeze events.

Summary: These websites show the current distribution of the Northern White Cedar, Sugar Maple, Paper Birch, and Black Ash respectively. They are maps created by the United States Department of Agriculture Forest Service to show the current distribution, projected future habitat, and predictor maps of these tree species. They are interactive maps where you can see climate change affecting the tree species with consideration of specific factors.

Paper Birch: Wiigwaasaatig

1. *Frumhoff, P.C.; McCarthy, J.J.; Melillo, J.M.; Moser, S.C.; Wuebbles, D.J. 2007. Confronting Climate Change in the U.S. Northeast: Science, Impacts and Solutions. Synthesis Report of the Northeast Climate Impacts Assessment (NECIA). Cambridge, MA: Union of Concerned Scientists.* Available at: http://www.northeastclimateimpacts.org/pdf/confronting-climate-change-in-the-u-s-northeast.pdf

Summary: This report discusses the Northeast and how they experience huge climate diversity within a small area. This area has also experienced drastic climate change since 1970, with a warming rate of almost 0.5 degrees Fahrenheit per decade. With the experienced climate warming there have been seen changes in the environment. This report was created to understand past and future climate change, to understand the potential effects that climate change could bring about.

Specific pages to note: **Pg. x:** Birch forests are predicted t shift dramatically northward in predicted climate change scenarios. **Pg. 49:** Figure 6. Shows the predicted shift birch is expected to take under two climate change scenarios. **Pg. 55:** Birch is projected to shift northward in either climate change scenario, with oak trees taking over to replace them. Climate change may leave birch more vulnerable to disease, pests, drought, wildfire, and storm damage. **Pg. 59:** The loss of birch with their colorful leaves in the fall could cause a decrease in tourism.

3. Hoene, N. 2010. Climate Change, an Ojibwe Perspective. The Seiche. Minnesota Sea Grant, March 2010. Available at http://www.seagrant.umn.edu/newsletter/2010_03.html.

Summary: Climate Change, an Ojibwe Perspective is an article discussing different Tribal members and their observation on the effects of climate change. Wild Rice, Maple Sugar, Birch, Pine, and other elements used in the Ojibwe culture are discussed on how climate change will impact them.

Specific pages to note: **Maple Sugar:** Sap has been running sooner; with a warmer climate it could start to run, and then stop. **Wild Rice:** It cannot stand extreme water level changes. **Coldwater Fish:** They will not stay if the streams warm by even a few degrees. **Tree:** A warmer climate means the loss of Birch, and potentially Sugar Maple if there is an increase in forest fires.

4. Iverson, L., A.M. Prasad, S.N. Matthews, M. Peters. 2008. Estimating Potential Habitat for 134 Eastern US Tree Species Under Six Climate Scenarios. Forest Ecology and Management 254: 390-406.

Summary: This article is a map of 134 tree species selected from random forests to study their responses to climate change. It is to show the current as well as potential future habitats of these species according to two emission scenarios with three climate models. Generally most specie habitats move northeast, with it being more drastically in a higher emission scenario. Generally there are quite a lot of species predicted to lose suitable habitat areas.

Specific Pages to Note: **Pg. 401:** Birch can sustain some habitat under low emissions but once under high emissions, it is eliminated. **Pg. 404:** Forests are expected to lose habitat under either scenarios.

Summary: This report was created by the United States Department of Agriculture to explain how the forests in northern Michigan will be affected by Climate Change. It specifically discusses the forests in the eastern and northern parts of the Upper Peninsula. It identifies major forest trends and stressors that are currently threatening Michigan forests. Using climate projections they identified the potential future impacts of climate change on forests.

Specific pages to note: **Pg. 96:** Table 17. Northern White Cedar decreases in both climate change scenarios. **Pg. 101:** Northern White Cedar experienced increased climate stress in both scenarios of climate change. As the climate warms it is expected to face increasing climate

related stress. **Pg. 121 & 128 & 134:** Northern White Cedar is expected to lose suitable habitat for survival. **Pg. 134:** Deer will inhibit the regeneration ability of Northern White Cedar which will add the future climate related stress. **Pg. 157:** Native American Tribes are likely to face decreased availability of culturally important tree species such as the Northern White Cedar.

Summary: This article is on Climate Change of the forests and forest habitats in Vermont. They have the projected climate change impacts that Vermont's forests in the south will experience including temperature, drought, lack of snow cover, and wildfire. The article gets over the current challenges that Vermont is facing and how they are trying to manage the impacts from climate change.

Specific Pages to Note: **Pg. 2 & 3:** Cedar seedling have a high mortality is greatest at temperatures above 90 degrees F, global warming could impact the mortality rate of cedar seedling. **Pg. 3:** Drought may have negative impacts on white cedar's regeneration abilities.

RESOLUTION NO. 257-16

Upon a motion by Treasurer Johnson and second by Representative Reynolds, the following was enacted:

WHEREAS, the Red Lake Tribal Council is the governing body of the Red Lake Band of Chippewa Indians, a federally recognized Indian Tribe; and

WHEREAS, pursuant to the Constitution and Bylaws of the Red Lake Band the Red Lake Tribal Council is entrusted with the responsibility to protect the human and natural environment throughout the diminished Reservation and the ceded territories; and

WHEREAS, chief among the Tribal Council's responsibility is the protection of water, which sustains all life, and the protection of clean water is our sacred responsibility as Anishinabe people; and

WHEREAS, manoomin, or wild rice, is also sacred to Anishinabe people, and because all waters are interconnected, even subtle changes in water quality or levels can profoundly harm the health of manoomin, which is a trust resource with federal protections; and

WHEREAS, private companies, including Enbridge are proposing and planning multiple oil and gas pipeline and other large infrastructure projects that would cross lands and waters where Tribal members gather wild rice and other natural resources, and where Tribal cultural resources are located; and

WHEREAS, construction of such large infrastructure poses a threat to waters, natural resources and cultural resources from disturbance during construction and permanent destruction by project activities; and

WHEREAS, oil pipelines in particular pose a unique threat to the Red Lake Nation where those pipelines cross over, under or through waters, wetlands and ecosystems on which tribal members depend for wild rice, fish, game, and other culturally-important natural resources; and

WHEREAS, impacts to natural and cultural resources from large-diameter pipeline construction include streambank degradation, increased sedimentation of waters, long-term wetland disruption, and destruction of fish and wildlife habitat corridors through permanent vegetation removal; and

WHEREAS, wild rice is particularly sensitive to changes in water levels, water quality, increased sedimentation, and pollutants; and

WHEREAS, pipeline proponents deliberately select new pipeline routes with the intent of avoiding all possible environmental review of pipeline projects; and

WHEREAS, as a result, routes for pipelines and other large infrastructure projects frequently avoid passing through Indian reservations and Tribal trust lands but still pass through treaty-ceded territories and tribal aboriginal lands where Tribal members hunt, fish, and gather, and where Tribal cultural resources are located; and

WHEREAS, Enbridge's proposed Line 3 Replacement Project will, if constructed, carry Canadian tar sands oil through a 36-inch diameter pipeline through pristine wild rice lakes, waters, rivers and interconnected aquifers located in the Red Lake Nation's ceded territory, as well as the headwaters of the Mississippi and two other major North American watersheds;

WHEREAS, many of those wild rice waters, rivers, lakes and aquifers are interconnected downstream and upstream with ecosystems which are the primary sources of natural resources important to Tribal members; and

WHEREAS, many of those interconnected waters flow through Red Lake treaty-ceded territories and aboriginal lands where Tribal members exercise reserved hunting, fishing and gathering rights and where cultural resources are located, or through Tribal trust lands, as well as the diminished Red Lake Reservation; and

WHEREAS, the Line 3 Replacement Project proposed route fastidiously avoids actually crossing any Indian Reservations or Tribal trust lands, yet will still impact important natural and cultural resources ; and

WHEREAS, the significance of treaty rights and treaty resources in Minnesota has been acknowledged in judicial decisions that have addressed those rights both on and off reservations; and

WHEREAS, current federal law and state law pertaining to the permitting of oil pipelines places greater emphasis on meeting the needs of the pipeline proponent than ensuring that natural resources, cultural resources, and Tribal rights, interests and resources are considered and protected; and

WHEREAS, current Army Corps of Engineers tribal consultation policy requires consultation with tribes on activities that occur within a tribe's aboriginal lands, regardless of land status; and

WHEREAS, the Army Corps of Engineers has looked to guidelines drafted in 1997 (Attached as Exhibit A) when ascertaining its trust responsibilities to Indian tribes and since that time there have been developments in the law both generally and specifically with respect to treaties with Minnesota tribes; and

NOW THEREFORE BE IT RESOLVED that the Tribal Council hereby requests that the U.S. Army Corps of Engineers initiate early and robust tribal consultation for any infrastructure projects proposed to be located within Red Lake aboriginal lands, regardless of land status or reservation status;

BE IT FURTHER RESOLVED that the Tribal Council hereby requests that such tribal consultations be initiated at the earliest stages of project proposal to allow tribes to identify tribal natural and cultural resources that may be impacted;

BE IT FURTHER RESOLVED that the Tribal Council hereby requests that the U.S. Army Corps of Engineers work with the Red Lake Nation and other Ojibwe tribes in Minnesota and Wisconsin to develop new Clean Water Act Section 404 permitting processes for wild rice waters in recognition of the special impacts created to wild resources by activities covered under Section 404;

BE IT FURTHER RESOLVED that the Tribal Council hereby requests that the U.S. Army Corps of Engineers seek all necessary authority to condition Section 404 permit approval over infrastructure projects occurring within tribal aboriginal lands with serious potential impacts to tribal cultural and natural resources on receipt of the informed consent of the impacted tribes; and

BE IT FINALLY RESOLVED that the Tribal Council hereby requests that the U.S. Army Corps of Engineers: (1) consult with the Red Lake Nation to update the guidelines (Exhibit A); (2) make a firm, unequivocal commitment that it will follow those guidelines and fulfill its trust obligations to Indian tribes; and (3) enter into an agreement with the Red Lake Nation to establish protocols for tribal input and consultation on proposed actions impacting tribal cultural and natural resources.

FOR : 9
AGAINST: 0

We do hereby certify that the foregoing resolution was duly presented and enacted upon at a Special Meeting of the Tribal Council held on November 30, 2016, with a quorum present, at the Red Lake Nation Headquarters, Red Lake.

Construction-Operations
Regulatory (94-01298-IP-DLB)

Mr. James Schlender
Executive Administrator
Great Lakes Indian Fish & Wildlife Commission
P.O. Box 9
Odanah, Wisconsin 54861

Dear Mr. Schlender:

As a result of issues that have arisen during our evaluation of a permit application by Crandon Mining Company to establish a mining operation near Crandon, Wisconsin, the St. Paul District has been asked by several Native American tribes to address the nature and extent of the Corps trust responsibilities toward Indian tribes in the Corps regulatory permitting process. I have indicated at past consultation meetings that I had requested guidance from Corps Headquarters to address this question.

Enclosed is an issue paper that provides the guidelines that the District will follow to insure that it fulfills its trust obligations. This paper, while very useful for illustrative purposes, may not resolve issues that are specific to any individual treaty or pending permit action.

I propose that we hold a consultation meeting in approximately 60 days. This will provide you time to review the paper and to develop any questions or concerns that you may have regarding these guidelines, as well as to how they will be applied in our review of the Crandon Mining Company permit application. I suggest that the consultation meeting be held in early December in Eau Claire, Wisconsin. Mr. Dave Ballman, of my staff, will coordinate with your staff in scheduling the meeting.

Please contact me at (612) 290-5300 if you have any questions.

Sincerely,

/S/

J. M. Wonsik
Colonel, Corps of Engineers
District Engineer

ISSUE PAPER
AND
DISTRICT RECOMMENDATION

THE AGENCY'S TRUST RESPONSIBILITIES TOWARD INDIAN TRIBES IN THE REGULATORY PERMITTING PROCESS

1. ISSUE. Work activities performed pursuant to permits issued under Section 404 of the Clean Water Act or Section 10 of the Rivers and Harbors Act have the potential to impact Indian treaty rights[1] and to impact resources owned or used by Indian Tribes. Because of this, questions have arisen about the Corps' trust obligations to Indian tribes with respect to the Corps' permitting processes. This paper shall attempt to delineate trust issues related to the permitting process and will attempt to set forth guidelines with respect to those issues[2]. A question and answer format will be used to accomplish this purpose.

2. **May the Corps issue a permit that will impinge on or abrogate treaty rights?**

No, treaty rights[3], absent consent of Congress, may not be impinged or abrogated[4]. As the

---

[1]The term "treaty rights", as used in this paper, includes not only rights derived from treaties, per se, but also rights derived from federal statutes, agreements executive orders and the like. The terms "Tribal resources" or "Treaty resources", as used in this paper, refers to resources that the Tribe, pursuant to a treaty, has a right to exploit and includes resources that they own and resources that they have a right to gather. The term "trust resources" refers to resources held in trust by the United States (the title is held by the United States) for the benefit of the Tribe.

[2]The paper, other than as may be useful for illustrative purposes, will not attempt to resolve issues that are specific to any individual treaty or pending permit action, but will attempt to formulate guidelines which will insure that the agency fulfils all of its trust obligations.

[3]It should be noted that the terms "treaty rights" and "treaty resources" are not synonymous. For example, a treaty that guarantees a tribe the right to hunt and fish on its reservation, the "treaty right" is the right to take the resource (game or fish), the "treaty resource"

SCANNED

Court held in *Northwest Sea Farms, Inc., v. U.S. Army Corps of Engineers*, 931 F. Supp. 1555 (W.D. Wash. 1996) 1519-1520:

> The Supreme Court has recognized "the undisputed existence of a general trust relationship between the United States and the Indian people." *United States v. Mitchell*, 463 U.S. 206, 225, 103 S.Ct. 2961, 2972, 77 L.Ed.2d 580 (1983). This obligation has been interpreted to impose a fiduciary duty owed in conducting "any Federal Government action"[5] which relates to Indian Tribes. *Nance v. Environmental Protection Agency*, 645 F.2d 701, 711 (9th Cir.), *cert. Denied*, 454 U.S. 1081, 102 S.Ct. 635, 70 L.Ed.2d 615 (1981), ... In previous cases, this Court has tacitly recognized that the duty extends to the Corps in the exercise of its permit decisions. *See e.g. Muckleshoot Indian Tribe v. Hall*, 698 F. Supp. 1504, 1523 (W.D.Wash.1988) (granting an injunction against the construction of a marina in consideration of the effect upon Indian treaty rights).
>
> In carrying out its fiduciary duty, it is the government's and subsequently the Corps', responsibility to ensure that Indian treaty rights are given full effect. *See e.g. Seminole Nation v. United States*, 316 U.S. 286, 296-297, 62 S. Ct. 1049, 1054-55, 86 L.Ed. 1480, 86 L.Ed.1777 (1942) (finding that the United States owes the highest fiduciary duty to protect Indian contract rights as embodied by treaties). Indeed, it is well established that only Congress has the authority to modify or abrogate the terms of Indian treaties. *United States v. Eberhardt*, 789 F.2d 1354, 1361 (9th Cir.1986). As such, the Court concludes that the Corps owes a fiduciary duty to ensure that the Lummi Nation's treaty rights are not abrogated or impinged upon absent an act of Congress.

3. How are treaty rights determined?

Treaty rights are determined on a case by case (treaty by treaty) basis. Each individual treaty or series of treaties must be examined to determine the specific rights provided by those treaties.

---

is the game or fish. Although courts have, almost universally held that treaty rights may not be impinged, they have not held that the resource may not be negatively impacted. See also question 6.

[4]Note, however, that the same Court that decided *Northwest Sea Farms, Inc.* issued an order in *Lummi Indian Nation v. Cunningham*, case No. C92-1023C on September 1, 1992, to the effect that before a claim that treaty rights have been impinged or abrogated is cognizable "the interference with the treaty right must reach a level of legal significance".

[5]A permit is a Federal Government action"

4. How are Indian treaties to be interpreted?

There are three basic rules of treaty construction. They are: (1) Ambiguities in treaties must be resolved in favor of the Indians, (2) Indian treaties must be interpreted as the Indians would have understood them at the time they consented to the treaty, and (3) Indian treaties must be construed liberally in favor of the Indians. This does not mean, however, that the treaties are to be construed in any manner that the Indians wish them to be construed. The rules of construction do not permit the clear intent of the treaties to be disregarded.

The Court in *Menominee Indian Tribe of Wisconsin v. Thompson*, 922 F.Supp. 184, (198-199), (W.D. Wis. 1996) described the rules of construction as follows:

> It is well known that Indian treaties must be interpreted as the Indians understood them, that doubtful expressions are to be resolved in favor of the Indians and that treaties must be construed liberally in favor of the signatory tribes. ... treaties are not to be construed by "the technical meaning of [their] words to learned lawyers, but in the sense in which they would naturally be understood by the Indians." *Id.*
>
> Determining the Indians' understanding may require expert testimony to explain the historical and cultural context in which the Indians viewed the treaty provisions. *See, e.g. McClanahan v. State Tax Comm'n of Arizona*, 411 U.S. 164, 174, 93 S.Ct. 1257, 1263, 36 L.Ed.2d 129 (1973) ... ("Doubtful expressions are to be resolved in favor of the weak and defenseless people who are the wards of the nation, dependent upon its protection and good faith."); *Winters v. United States*, 207 U.S. 564, 576-77, 28 S.Ct. 207, 211, 52 L.Ed. 340 (1908) ("ambiguities occurring [in treaties] will be resolved from the standpoint of the Indians").
>
> It is true that "[t]he cannon of construction regarding the resolution of ambiguities ... does not permit reliance on ambiguities that do not exist; nor does it permit disregard of the clearly expressed intent of Congress." *South Carolina v. Catawba Indian Tribe*, 476 U.S. 498, 506, 106 S.Ct. 2039, 2044, 90 L.Ed.2d 490 (1986). See also *Amoco Production Co. V. Gambell*, 480 U.S. 531, 555, 107 S.Ct. 1396, 1409, 94 L.Ed.2d 542 (1987) (citing *Catawba Indian Tribe*); *Choctaw Nation*, 318 U.S. at 432, 63 S.Ct. At 678 ("even Indian treaties cannot be rewritten or expanded beyond their clear terms to remedy a claimed injustice or to achieve the asserted understanding of the parties").

Moreover, many of the issues of treaty construction that are likely to arise in the permitting process, have already been determined by the Courts[6]. Thus, the first step in

---

[6]Even if the case law is not dispositive of the specific issue, it may provide rationale or additional information which will aid in the decision process. Additionally, it is recommend that Office of Counsel (or similar resource) be consulted before making a determination, in questionable cases, whether a treaty right exists or does not exist and whether the proposed

construing a treaty should be to review any Court decision that may be relevant.

5. How can we determine if treaty rights may be an issue with respect to a specific permit application?

The geographic extent[7] of all treaty rights and Tribal resources should be known to the regulatory staff. If the proposed activity could have any effect within that geographic area the treaties should be reviewed to determine if treaty rights may be affected. A determination should also be made as to whether the proposed activity may affect Tribal resources. Most importantly, the Indian Tribes that may be affected by the permitted activity should be apprised of the permit application and be given the opportunity to comment or consult with the Corps. If any Tribe asserts that the proposed permit activity would impinge on or abrogate its treaty rights or would negatively impact its resources, it should be requested[8] to provide all substantiating information it has available as to: (1) the existence of treaties, (2) claimed treaty rights, (3) any Court cases relevant to the Tribe's assertions, (4) an explanation of how the proposed activity would violate treaty rights, (5) identification of any Tribal resources that may be impacted, (6) an explanation of how the proposed activity would impact Tribal resources, and (7) a description of how the proposed activity would impact the Tribe[9]. BIA should also be informed of any proposed activity (needing a Corps permit) that might impact Tribal resources and should be requested to identify any treaty rights or Tribal resources that may be impacted by the proposed permit.

6. Does the Corps have a trust responsibility to protect Tribal resources from environmental degradation that may result from the proposed permit activity?

The Corps must consider the effect that the activity needing a Corps permit would have on the Tribe's resources, however, the fact that the Tribe's resource may be degraded, or reduced in value or utility, does not necessarily compel denial of the permit. This principle was explained by the Court in *Nez Perce Tribe v Idaho Power Co.*, 847 F.Supp. 791 807-813 (D.Idaho 1994) in a

---

permit will or will not violate those rights.

[7]Including the area within the external boundaries of any Indian reservation and the geographic area in which usufructuary rights, if any, may be exercised.

[8]The Tribes are not required to respond.

[9]This request would be made to afford the Tribes every practicable opportunity to present their views. Neither the failure of the Tribes to respond nor a response from the Tribes relieves the Corps of its obligation to consider all impacts the proposed activity would have on any treaty rights or any impacts to Tribal resources that Corps is aware of, or reasonably should have been aware of. See also *Pueblo of Sandia v. United States*, 50 F.3d 856 (10th Cir. 1995).

case concerning permanent usufructuary rights[10], as follows:

> ... In other words, the Tribe argues that developments such as dams which damage, reduce or destroy the fish runs violate their 1855 Stevens treaty fishing rights and entitles them to an award of monetary damages.
>
> b) *Treaty Rights to Preservation of Fish Runs*
>
> The ultimate issue presented is whether the treaty provides the Tribe with an absolute right to preservation of the fish runs in the condition existing in 1855, free from environmental damage caused by a changing and developing society. Only if such a right exists is the Tribe entitled to an award of monetary damages.
>
> The parties have cited, and the Court's own independent research has disclosed only three cases which directly address this ultimate issue. *United States v. Washington* (hereinafter *"Washington 1982"*), 694 F.2d 1374 (9th Cir. 1982); *Muckleshoot Tribe v Puget Sound Power and Light*, CV No. 472-72C2V (W.D. Wash.1986); and *Nisqually Tribe v. City of Centralia*, No. C75-31 (W.D. Wash.1981). However, *Washington 1982* was vacated by the Ninth Circuit on other grounds in a subsequent en banc decision. *United States v. Washington*, 759 F.2d 1353 (9th Cir. 1985). *Muckleshoot Tribe v. Puget Sound* expressly relied on the *Washington 1982* opinion which was not vacated until after the decision in *Muckleshoot* was issued. Therefore, it appears that this Court is required to address and determine an issue of first impression without the benefit of any binding guidance and direction. ...
>
> ... State regulation cannot discriminate against the Indian fishery. *Puyallup II*, 414 U.S. [44] at 48, 94 S.Ct. [330] at 333 [38 L.Ed.2d 254 [(1973)]. This principle is broad enough to encompass discriminatory granting of permits for projects with potentially adverse environmental effects.
>
> *Id.* At 1382.
>
> In addition, the Ninth Circuit rejected the trial court's conclusion that other previous cases implied a general right to environmental protection of the fish: ...
>
> Thus, according to the Ninth Circuit's persuasive reasoning in *Washington 1982*, the states may allow or even authorize development which reduces the number of fish in the annual runs as long as such action does not discriminate against treaty fishermen in determining what development will be authorized. Although the opinion was vacated on other grounds, the Court agrees with the

---

[10]The treaty at issue in the case has been interpreted as creating permanent usufructuary rights (non-exclusive) to fish in all of the Tribes usual and customary places. Not all usufructuary rights are permanent as some are subject to termination upon the occurrence of a defined event. For example, Chippewa usufructary rights with respect to territory ceded by them to the United States are terminated or extinguished whenever the land is owned by private entities rather than the public. The (trust) duty to mitigate for damage to resources that may be harvestable pursuant to permanent usufructuary rights discussed by the Court in *Nez Perce* may not be applicable to usufructuary rights that can be terminated or extinguished in their entirety. .

legal analysis in *Washington 1982*. In the Court's view, the Stevens treaties do not protect the Indians from degradation of the fish runs caused by development which is not part of a pattern of discrimination against Indian treaty fish runs.

... In the Court's view, the 1855 treaty does not provide a guarantee that there will be no decline in the amount of fish available to take. The only method that would guarantee such protection would be to prevent all types of development, whether or not it is discrimatory of Indian treaty rights. The Stevens treaties simply do not provide the Tribe with such assurance or protection.

... Stevens treaties require that any development authorized by the states which injure the fish runs be non-discrimatory in nature *see Fishing vessel*, 443 U.S. 658, 99 S.Ct. 3055, 61 L.Ed.2d 823 but does not, however, guarantee that subsequent development will not diminish or eventually, and unfortunately, destroy the fish runs.

7. Does the Corps trust responsibility to Indian tribes require mitigation for impacts to off reservation resources that the Tribes have a right to harvest (usufructuary rights)?

The answer to this question depends on the nature of the usufructuary rights reserved or held by the Tribes. All usufructuary rights are not alike. For example, courts have held that a number of Tribes in the Pacific Northwest have usufructuary rights that are permanent in nature and are not subject to termination[11]. Those rights were held to have both a geographic component[12] and a component that entitled the Tribes to take a share of the available fish. Those courts have also held that while the Tribes were not entitled to be protected against off reservation activity that would result in a reduction of available fish, they were entitled to reasonable steps to mitigate adverse impacts from the activity.[13] The theoretical basis for the holding that reasonable mitigation is required was explained in *United States v. State of Washington*, 506 F.Supp. 187, 203 (1980)[14] as follows:

> At the outset the Court holds that implicitly incorporated in the treaties' fishing clause is the right to have the fishery habitat protected from man-made

---

[11]Other than by an Act of Congress.

[12]The right to fish forever in certain locations defined in the Treaty.

[13]"We do not find such an obligation in the treaty. Where the decision to allow development is not tinged with any discrimatory animus, the treaty fishing clause, as we read it, does not require compensation of the Indians on a make whole basis if reasonable steps, in view of the available resources and technology, are incapable of avoiding a reduction in the amount of available fish." *U.S. v. State of Washington*, 694 F.2d 1374, 1386 (1983)

[14]The Court's decision was vacated by the Ninth Circuit on other grounds in "*U.S. v. State of Washington*, 694 F.2d 1374. See also question 6.

despoilation. Virtually every case construing this fishing clause has recognized it to be the cornerstone of the treaties and has emphasized its overriding importance to the tribes. ... The Indians understood, and were led by Governor Stevens to believe, that the treaties entitled them to continue fishing in perpetuity and that the settlers would not qualify, restrict, or interfere with their right to take fish. ...

In contrast to the Pacific Northwest cases, the Chippewa in Wisconsin and Minnesota have been found to have usufructuary rights to hunt, fish and gather that are extinguished upon the land passing to private ownership[15]. Thus the underlying rationale in the Pacific Northwest cases - perpetual usufructuary rights - for requiring mitigation, as a trust responsibility, is not present with respect to the Chippewa's usufructuary rights. Moreover, a determination that the United States' trust obligations would require it to ensure that mitigation would be performed would be logically inconsistent with case law which has held that the usufructuary rights were extinguished when the land over which they originally could have been exercised passed to private ownership. Under the relevant case law no compensation would be due the Tribes, even if all of the land passed to private ownership, as it was understood that usufructuary rights "were subject to and limited by the demands of the settlers." *Lac Courte Oreilles Band v. State of Wisconsin*, 760 F.2d 177, 183 (1985)

Therefore, the specific usufructuary right in question should be examined to determine if mitigation would be required as a trust obligation. However, even if it is determined that mitigation would be required, it is not unlikely that mitigation that is or would be required in conjunction with the permit, even absent a trust responsibility,[16] would be sufficient to satisfy any Government trust obligation to mitigate.[17]

8. Does the Corps trust responsibility to Indian Tribes require mitigation for adverse impacts to Tribal resources on reservations?

Each treaty at issue must be reviewed to determine what is or is not required under that treaty. Under the rationale of the Pacific Northwest cases it would appear that mitigation, to the extent reasonable and practicable is owed. However, those cases do not indicate that there is an environmental servitude owed the Tribes such that mitigation must ensure that there is no net adverse effect resulting from the federal action. In fact, the Court in *United States v. State of*

---

[15] *Lac Courte Oreilles Band, Etc. v Voigt*, 700 F.2d 341 (1983) and *Lac Courte Oreilles Band v. State of Wisconsin*, 760 F.2d 177.

[16] Mitigation that would be required of the applicant even if there were no usufructuary rights or trust obligation to mitigate.

[17] See *Pyramid Lake Paiute Tribe v. U.S. Department of Navy*, 898 F.2d 1410 (9th Cir. 1990); *Havasupai Tribe v. United States*, 752 F. Supp. 1471 (D. Ariz. 1990); and *Nance v. Environmental Protection Agency*, 645 F.2d 701 (1981)

Washington, 694 F.2d 1374 (1982) has indicated that a resource may be rendered valueless without abrogation of treaty rights or trust responsibilities[18]. As stated by that Court at page 1381 "Any right may be subject to contingencies which would render it valueless." and at page 1382:

> The spectre the district court raises of tribal fishermen unprotected by the environmental right dipping their nets into the water and bringing them out empty, 506 F.Supp. at 203, cannot alter the scope of *Fishing Vessel*. Only the extension of the servitude to ban even non-discriminatory development occurring both within and without treaty fishing areas assure against any decline in the amount of fish taken. The treaty does not grant such assurance.

It is also not unlikely that any trust obligation owed to require mitigation would be satisfied by mitigation that would be required in conjunction with the 404 permit process, absent a trust obligation.

Accordingly, mitigation, to the extent it is reasonable and practicable, for impacts to Tribal resources sited on reservations should be required.

9. May an activity whose impact to a reservation's resources be such that it would defeat the purpose for which the reservation was established be permitted?

Before one can begin to address this question, in practice, the terms of the treaty in question must be examined to determine if the Treaty specifically contemplates the activity to be permitted and if that activity, under the terms of the treaty takes precedence over or is subservient to the interests of the Tribe[19] Assuming the treaty is not dispositive, the following is applicable.

I am not aware of a line of cases directly addressing this issue; however, *Pyramid Lake Paiute Tribe of Indians v. Morton*, 354 F.Supp. 252 (1973) gives us guidance as to how one court decided the issue and may be illustrative of how such issues would be decided in the future. The case concerned the Department of Interior's regulation, which the Tribe contended delivered "more water to the District than required by applicable court decrees and statutes, and improperly diverts water that otherwise would flow into nearby Pyramid Lake located on the Tribe's

---

[18]This discussion is not applicable to impacts which would defeat the purpose for which the reservation was established.

[19]See *Sokaogon Chippewa Community v. Exxon Corp.*, 805 F.Supp. 680, 706 (E.D.Wis, 1992) "If the Sokoagon were to prevent Exxon from mining on the subject territory, it would be in contravention of the very considerations prompting the two treaties. Even assuming that the Sokaogon have rights in the land, the language and intent of the 1842 and 1854 Treaties demand that mineral development should take precedence over those rights.

reservation." Although the Court could have analyzed the case under the Winters doctrine[20] It chose not to do so. The Court noted, at pages 254-255, that:

> This Lake has been the Tribe's principal source of livelihood. Members of the Tribe have always lived on its shore and have fished its waters for food. ...
>
> Recently, the United States, by original petition in the Supreme Court of the United States, filed September, 1972 claims the right to use sufficient water of the Truckee River for the benefit of the Tribe to fulfill the purposes for which the Indian Reservation was created, "including the maintenance and preservation of Pyramid Lake and the maintenance of the lower reaches of the Truckee as a natural spawning ground for fish and other purposes beneficial to and satisfying the needs of the Tribe. ...

The Court then determined (page 256) that:

> ... The Secretary's duty was not to determine a basis for allocating water between the District and the Tribe in a manner that hopefully everyone could live with for the year ahead. This suit was pending and the Tribe had asserted well-founded rights. The burden rested on the Secretary to justify any diversion of water from the Tribe with precision. It was not his function to attempt an accommodation.
>
> In order to fulfill his fiduciary duty, the Secretary must insure, to the extent of his power that, that all water not obligated by court decree or contract with the District goes to Pyramid Lake.

Accordingly, should the Corps determine that an activity needing a Corps permit would impact the reservation's resources to an extent that they would defeat the purpose for which the reservation was established the permit should be denied.[21]

10. What is the Winter's doctrine and is it applicable to permit decisions?

Felix S. Cohen's Handbook of Federal Indian Law, 1982 Edition, pages 575 to 576 offers a good explanation of the doctrine:

> The Supreme Court first articulated this doctrine in *Winters v. United States* in 1908 and reaffirmed it in 1963 in *Arizona v. California. Cappaert v.*

---

[20] *Winters v. United States, 207 US 564, (1908)*

[21] It is likely that if the impacts were so great as to defeat the purpose of the reservation that, even without considering the Corps' trust obligations, the permit would be denied as not being in the public interest. (A permit whose impact would deprive any community of the ability to maintain a moderate living standard is not likely to be in the public interest.)

United States contains the Court's most succinct and lucid statement of the governing principles of reserved water rights:

> This Court has long held that when the Federal Government withdraws its land from the public domain and reserves it for a federal purpose, the Government, by implication, reserves appurtenant water then unappropriated to the extent needed to accomplish the purpose of the reservation. In so doing the United States acquires a reserved right in unappropriated water which vests on the date of reservation and is superior to the rights of future appropriators. ... The doctrine applies to Indian reservations and other Federal enclaves, encompassing water rights in navigable and nonnavigable streams.
>
> In determining whether there is a federally reserved water right implicit in a federal reservation of public land, the issue is whether the Government intended to reserve unappropriated and thus available water. Intent is inferred if the previously unappropriated waters are necessary to accomplish the purpose for which the reservation was created.

This doctrine arose and has been applied extensively in appropriative water law states (generally western states that have limited supplies of water). The doctrine has not been applied to riparian water law states and may not be applicable to them.

11. When, in the permitting process sequence, should the Corps trust obligations be considered?

Since the Tribal trust issues, alone, may be determinative[22] of the outcome of the permit decision, those issues should be considered immediately after or in conjunction with consideration of the avoidance issue.

12. If the Tribal trust issues are not dispositive of the permitting decision, do we need to consider the Tribe's concerns further?

Yes. The Tribal concerns and the impacts of the proposed activity on Tribal resources should be considered in the public interest review just as any other similarly sized community would be. Such consideration should not be evaluated based on Tribal trust responsibility considerations[23] but should take into account the relative impact the proposed activity would have

---

[22]For example, if the permitted activity would violate a treaty provision, the permit application would be denied.

[23]These considerations should have been addressed previously.

on the community[24]. The same impact to natural resources may have a greater effect on individual Indians than it would on non-Indians, not only because of greater dependence on those resources, but also because the individual Indian may be more closely tied to the defined land area than his non-Indian counterpart. Additionally, any spiritual or cultural impact to the Tribe that would result from the proposed permit activity should be evaluated in the public interest review.

13. Should the Corps apply different criteria to permit applications for activities within a reservation's exterior boundaries than would be applied to a permit application for activities outside a reservation's exterior boundaries?

No. The criteria applied should be the same. However, it is very likely that an activity that is sited within the reservation's exterior boundaries would have a greater impact on Tribal resources than would an activity that is sited off reservation. Moreover, the applicant would still have to comply with all applicable local regulations, thus the Tribe may be able to impose its requirements[25] on the applicant. Such requirements would be independent of and in addition to any Corps' permit requirement or condition. Further, if the Tribe has jurisdiction over the activity and exercises its jurisdiction to prohibit the activity[26] the permit application to the Corps should be denied without prejudice.

14. Who is the Federal Trust Obligation owed to?

The Trust obligation is owed to Federally Recognized Indian Tribes.

Edwin C. Bankston
District Counsel

---

[24]For example, an activity that would diminish the supply of game may affect Indian communities to a greater degree than non-Indian communities, because the Indian community may be more dependent on game than the non-Indian community. This greater importance to the Indian community should be factored into the evaluation.

[25]Including preventing the activity if the Tribe has sufficient authority to do so.

[26]Such as denying a required Tribal permit.

Re: Sandpiper Pipeline and Line 3 Route

Dear Mr. MacAlister,

I am writing to you in regards to the Proposed Sandpiper and Line 3 routes. The Cultural Resource Program of the Minnesota Indian Affairs Council (MIAC) is concerned with the proposed routes through the northern half of Minnesota. Our concern is that the proposed preferred routes will go through the richest cultural resources areas within the State of Minnesota. As established by MN Statue 307.08, MIAC has the joint responsibility under the law to protect all American Indian Burial Sites within the State. The potential of adverse effects on identified burial and archaeology sites and important sacred sites as well as sites that have yet to be identified is too great for us not to be concerned.

Thank you for your attention to this important matter.

Re: Comments to Scoping Request of MN Department of Commerce

Dear Ms. MacAlister,

We appreciate the conversation that was had on February 16th, 2016 at the Leech Lake Division of Resource Management in Cass Lake on the Leech Lake Indian Reservation. To ensure clarity my letter in no way speaks for the White Earth government or any other Minnesota tribal entity, it is only meant to clarify and ensure the conversation was captured correctly. Below I have bulleted all the major discussion items from our February 16th, 2016 conversation;

- The Line 3 Project application is not only a requesting of a new corridor but reviewing whether current placement is appropriate and also the decommissioning of the existing Line 3 which a portion would take place within Indian country. Leech Lake Band of Ojibwe would be the decision maker on how any decommissioning would be implemented within our regulator boundaries.

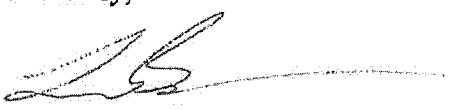
- Scoping of the alternative route through Indian country should involve the decision makers along that route. In this case ACOE, CNF, BIA and EPA.

- If these decision makers are not included in the scoping process as decision makers it makes the NEPA process incomplete and no federal agency can use the State EIS document.

- The alternative route would have an incomplete review of a section of 46 miles through the LLR and my recommendation is that it is dropped from the alternative routes because of the lack of decision making authority.

- All appropriate regulators along a route should be listed as cooperatives agencies because the permits and activities needed will and should be scoped in any MEPA/NEPA process.

Why do Tribal and Federal trustees need to be cooperative agencies when scoping involves Indian Country?



- Because Tribes are adversely affected by climate change because of the subsistence lifestyles and cultural identification.
- Environmental Justice issues such as why would a route currently with 6 crude pipelines, 2 natural gas pipelines, railroad corridor and major powerline corridor **even be considered.**
- Historically it is easier for applicants of such permits to get approved permits through the lands of minority people who are perceived to historically have a limited voice.
- The socio-economic impacts to natural resource access and loss of resources mitigation would be required to offset these impacts.
- NEPA requires that decision making authorities be addressed up front and not as general public entities but instead as cooperating agencies.
- In this case LLBO is a decision maker along alternative route through LLR with our federal partners and we are not cooperating agencies to the NEPA document which would be a fundamental flaw in the NEPA process or document.
- The Alternative routing issue can be easily addressed by simply dropping the route through LLR from consideration.

Why is the cooperative approach to decision making important through Indian country?

- Shared information
- Accurate and defensible Studies/NEPA Documents
- Reach Common Decisions in multiple jurisdictional routes

In closing it is our hope that the Minnesota Department of Commerce recognizes that to properly scope the existing corridor for Line 3 as an alternative route that there is a whole spectrum of issues and regulators would need to be addressed outside of a Minnesota State Environmental Impact Statement. If there are questions or comments please feel free to contact my office at (218)-335-7400.

Sincerely,

Levi Brown, Director

Saint Paul, Minnesota 55101

Re: **Final Scoping Decision**

Dear Mr. Wolf,

I'm writing to ensure decision makers are not make conflicting decisions and clarity between our two entities in regards to work that Minnesota Department of Commerce (MNDOC) is preforming on the Line 3 Replacement Proposed Final Scoping Decision Document undertaken at the order of the Minnesota Utilities Commission (MNPUC). There are several flaws with the document which have yet to be rectified by MNDOC which I have specifically outlined in the bullets;

- Scoping Document lists Tribal Coordination with the 2 sentences injected in the Environmental Review Process Section 2.0 of the Proposed Scoping Decision Document. There are two standalone Route Alternatives that are listed in your scoping document that cross the Leech Lake Indian Reservation (LLIR) this section does not accurately portray the role of Leech Lake Band of Ojibwe and other decision makers within the LLIR.

- Page 13, of the Proposed Scoping Decision Document states that RA-03 AM was eliminated because it was based on Screening Analysis of economic and regulatory feasibility, Environmental impacts and socioeconomic effects. Routes RA- 07 and RA - 08 should be dropped as well because they too overriding reasons such as regulatory feasibility (See Attached Leech Lake Resolution) that eliminates these routes from consideration.

- Section 3.3.5 of the Proposed Scoping Decision Document discusses evaluating removing line in place and replacing it with new pipe with no discussion with other governmental decision makers to discuss whether that would be regulatory feasible.

- The First Paragraph on page 19 of the Proposed Scoping Decision Document is not only inaccurate it seems to have a mischievous intend to escape the issue that the Leech Lake Band of Ojibwe and other federal agencies will be issuing permits and making decision if

RA -07 and RA-08 are selected. None of the required permits or approval decisions is listed in section 7.0 which the document is portraying. Yet all the requirements for the Applicants proposed route are listed.

- The State Environmental Impact Statement (EIS) will be analyzing the removal of existing line and construction of pipeline in same trench and yet does not list any of those permits and decisions that will have to take place within the exterior boundaries of the LLIR.

- Section 4.4.4.3 Wild Rice and Other Tribal Resources There is mention of Leech Lake Band of Ojibwe hunting and fishing agreement with the State of Minnesota which clearly states that LLBO has exclusive authority to regulate Wild rice within the exterior boundaries of the LLIR.

I understand that this scoping document is being drafted for state use but strongly urge you share these issues with alternative routes or lack of information with the decision makers to ensure that integrity of the EIS is protected. I'm also aware there was not a public meeting on the LLIR when developing this state document which has selected two alternatives to be scoped that lie within the LLIR. In closing Routes RA-07 and RA-08 cross an Indian reservation and/or the National Forest which it shares a common border and the document which state officials will be making a decision fail to address this in any shape or form. If there are questions or comments please contact myself at (218)-335-7400.

Sincerely,

Levi Brown, Director

St. Paul, Minnesota 55101

Re: MN-PUC Docket No. PL6668/CN-13-473

To Tracy Smetana:

The Leech Lake Band of Ojibwe (the "Band") is in receipt of your letter dated October 4, 2013 regarding the Notice of Certificate of Need Application for the Sandpiper Pipeline Project to Chairwoman Carri Jones. I am writing this letter regarding the proposed alternate route, which runs through the Leech Lake Indian Reservation (the "Reservation").

Enbridge Pipelines (North Dakota) ("Enbridge") does not have legal or regulatory approval to expand its existing corridor through the Reservation. I understand that Minnesota State law may require the Public Utilities Commission ("PUC") to have applicants outline a preferred route and an alternate route, but the Band needs to inform the PUC and the State of Minnesota at this early stage that Enbridge **does not** have legal or regulatory approval to build an additional pipeline across the Reservation. Therefore, I respectfully request that the PUC insist on a new alternate route that does not enter the exterior boundaries of the Reservation.

Enbridge lists the route through the Reservation as an "alternate route" and not the "preferred route." However, the "alternate route" is not an alternate at all as it is an impossible route. The perplexing aspect of this situation is that Enbridge is fully aware that it has neither the legal nor regulatory capability to build another pipeline through the Reservation, and should have listed their alternate route as a route that does not enter the exterior boundaries of the Reservation.

The reason Minnesota law requires applicants to list both a preferred route and an alternate route is in the event the preferred route does not work for one reason or another. Because Enbridge's proposed alternate route is a legal impossibility at this time, I respectfully ask the PUC to insist on a new alternate route that does not enter the Reservation.

RESOLUTION 32-17

WHEREAS, the Minnesota Chippewa Tribal Executive Committee is the duly elected governing body of the Minnesota Chippewa Tribe, comprised of six member reservations (Bois Forte, Fond du Lac, Grand Portage, Leech Lake, Mille Lacs and White Earth), each of which is separately recognized by the United States as an Indian tribe; and

WHEREAS, the Revised Constitution and Bylaws of the Minnesota Chippewa Tribe provides that the purposes of the tribal organization under the Act of June 18, 1934 (48 Stat. 984) include the conservation of tribal resources and promotion of the general welfare of members of the Tribe; and

WHEREAS, water sustains all life, and the protection of clean water is our sacred responsibility as Anishinabe people; and

WHEREAS, manomin, or wild rice, is also sacred to Anishinabe people, and because all waters are interconnected, even subtle changes in water quality or levels can profoundly harm the health of manomin, which is a trust resource with federal protections; and

WHEREAS, private companies are proposing and planning several oil and gas pipeline and other large infrastructure projects that would cross lands and waters where Tribal members gather wild rice and natural resources, and where Tribal cultural resources are located; and

WHEREAS, construction of such large infrastructure poses a threat to waters, natural resources and cultural resources from disturbance during construction and permanent destruction by project activities; and

WHEREAS, oil pipelines in particular pose a unique threat to Ojibwe in Minnesota where those pipelines cross over, under or through waters, wetlands and ecosystems on which Ojibwe depend for wild rice, fish, game, and other culturally-important natural resources; and

WHEREAS, impacts to natural and cultural resources from large-diameter pipeline construction include streambank degradation, increased sedimentation of waters, long-term wetland disruption, and destruction of fish and wildlife habitat corridors through permanent vegetation removal; and

WHEREAS, wild rice is particularly sensitive to changes in water levels, water quality, increased sedimentation, and pollutants; and

WHEREAS, pipeline proponents deliberately select new pipeline routes with the intent of avoiding all possible environmental review of pipeline projects; and

WHEREAS, as a result, routes for pipelines and other large infrastructure projects frequently avoid passing through Indian reservations and Tribal trust lands but still pass through treaty-ceded territories and tribal aboriginal lands where Tribal members hunt, fish, and gather, and where Tribal cultural resources are located; and

WHEREAS, Enbridge's proposed Line 3 Replacement Project will, if constructed, carry Canadian tar sands oil via 36-inch diameter pipeline through pristine wild rice lakes, waters, rivers and interconnected aquifers of Minnesota including the headwaters of the Mississippi and two other major North American watersheds; and

WHEREAS, many of those wild rice waters, rivers, lakes and aquifers are interconnected downstream and upstream with ecosystems which are the primary sources of natural resources important to Tribal members; and

WHEREAS, many of those interconnected waters flow through Ojibwe treaty-ceded territories and aboriginal lands where Tribal members exercise reserved hunting, fishing and gathering rights and where cultural resources are located, or through Tribal trust lands and Reservations; and

WHEREAS, the Line 3 Replacement Project proposed route fastidiously avoids actually crossing any Indian Reservations or Tribal trust lands yet will still impact important natural and cultural resources; and

WHEREAS, the significance of treaty rights and treaty resources in Minnesota has been acknowledged in judicial decisions that have addressed those rights both on and off reservations; and

WHEREAS, current federal law and state law governing permitting of oil pipelines places greater emphasis on meeting the needs of the pipeline proponent than ensuring that natural resources, cultural resources, and Tribal rights, interests and resources are considered and protected; and

WHEREAS, current Army Corps of Engineers tribal consultation policy requires consultation with tribes on activities that occur within a tribe's aboriginal lands, regardless of land status; and

WHEREAS, the Army Corps of Engineers has looked to guidelines drafted in 1997 (Attached as Exhibit A) when ascertaining its trust responsibilities to Indian tribes and since that time there have been developments in the law both generally and specifically with respect to treaties with Minnesota tribes; and

NOW THEREFORE BE IT RESOLVED that the Tribal Executive Committee hereby requests that the U.S. Army Corps of Engineers initiate early and robust tribal consultation for any infrastructure projects proposed to be located within Ojibwe aboriginal lands, regardless of land status or reservation status; and

BE IT FURTHER RESOLVED that the Tribal Executive Committee hereby requests that such tribal consultations be initiated at the earliest stages of project proposal to allow tribes to identify tribal natural and cultural resources that may be impacted; and

BE IT FURTHER RESOLVED that the Tribal Executive Committee hereby requests that the U.S. Army Corps of Engineers work with Ojibwe tribes in Minnesota and Wisconsin to develop new Clean Water Act Section 404 permitting processes for wild rice waters in recognition of the special impacts created to wild rice resources by activities covered under Section 404; and

BE IT FURTHER RESOLVED that the Tribal Executive Committee hereby requests that the U.S. Army Corps of Engineers seek all necessary authority to condition Section 404 permit approval over infrastructure projects occurring within tribal aboriginal lands with serious potential impacts to tribal cultural and natural resources on receipt of the informed consent of the impacted tribes; and

BE IT FINALLY RESOLVED that the Tribal Executive Committee hereby requests that the U.S. Army Corps of Engineers: (1) consult with the Minnesota Chippewa Tribe and its constituent Bands to update the guidelines (Exhibit A); (2) make a firm unequivocal commitment that it will follow those guidelines and fulfill its trust obligations to Indian tribes; and (3) enter into agreements with the MCT or a constituent Band to establish protocols for tribal input and consultation on proposed actions impacting tribal cultural and natural resources.

We do hereby certify that the foregoing Resolution was duly presented and acted upon by a vote of 9 For, 1 Against (Dennis Morrison), 0 Silent, at a Special Meeting of the Minnesota Chippewa Tribal Executive Committee, a quorum present, held on November 30, 2016 via electronic polling, Cass Lake, Minnesota.

John Linc Stine, Commissioner
Minnesota Pollution Control Agency
520 Lafayette Road North
St. Paul, MN 55155-419

Re: Definition of "waters used for the production of wild rice"; wild rice water quality standards

Dear Commissioner Stine:

The Minnesota Chippewa Tribe appreciates having the opportunity to continue discussions with your agency regarding the definition of "waters used for the production of wild rice." We commend the Minnesota Pollution Control Agency (MPCA) for the work done to clarify this definition and to strengthen protection for this critical resource. As you know, wild rice is a culturally significant resource for the tribes in Minnesota. From historical reports,[1] Band member accounts,[2] and current Minnesota Department of Natural Resources ("DNR") and tribal reports,[3] wild rice has declined significantly throughout Minnesota, and in southern Minnesota wild rice has virtually disappeared. Minnesota tribes have a unique relationship with the state regarding the protection of wild rice, as demonstrated through multiple rulemaking processes[4] and executive orders.[5]

[5] *See, e.g.*, Executive Order 13-10, "Affirming the Government-to-Government Relationship between the State of Minnesota and the Minnesota Tribal Nations: Providing for Consultation, Coordination, and Cooperation."

Maintain the existing sulfate criterion for protection of wild rice waters

Minnesota tribal staff have participated in and followed closely the MPCA's research program related to the existing sulfate criteria for protecting wild rice waters[6]. Our thorough review and interpretation of the research results for the state-led hydroponics studies, the field surveys, the mesocosm studies, and the sediment studies leads to our conclusion that the existing federally approved sulfate criterion is well-supported by multiple lines of evidence, and should be maintained. There is no scientific defensible basis for raising this sulfate limit, which is the clear benchmark required by the US Environmental Protection Agency for considering approval of a revised criterion[7], as was clearly communicated to the Minnesota legislative body in 2011[8].

The MPCA proposed approach for listing wild rice waters is inconsistent with the Clean Water Act

The Minnesota tribes have fundamental concerns regarding MPCA's proposed approach for meeting the intent of the 2011 state legislation that directs the agency to establish criteria considering "history of wild rice harvests, minimum acreage, and wild rice density."[9] In January of 2014, the Fond du Lac, Grand Portage, Leech Lake, White Earth and Bois Forte Bands communicated clear concerns for the agency's proposed 'watch list' approach in letters to MPCA; specifically, that this approach would violate the Clean Water Act (the Act) and Minnesota water quality standards (WQS). The agency had proposed to create a 'watch list' for those wild rice waters listed by the DNR for which the state lacked specific acreage and/or stand density measurements; only those waters with quantified stands would be formally listed as wild rice waters. The DNR list of Minnesota wild rice waters[10] was compiled as part of a legislatively directed study of the threats to wild rice in Minnesota, and represented significant contributions from Minnesota tribal resource management staff. State and tribal staff also explicitly qualified this 2008 compiled listing as 'not comprehensive', and that it would be continuously updated as new data became available.

Under the Act, the Nation's waters are to be restored and maintained for the protection and propagation of fish, shellfish, and wildlife, and for recreation in and on the water.[11] The goal of a water quality standards program is to restore and maintain the chemical, physical, and biological integrity of the Nation's waters.[12] States and authorized Tribes adopt water quality

[12] *Id.*

standards to protect public health, enhance the quality of water, and serve the purposes of the Clean Water Act[13] and are free to add use classifications, as well as adopt any use classification system they see as appropriate (with the exception of waste transport and assimilation, which are not acceptable uses in any case). Among the uses listed in the Act, there is no hierarchy.

A primary objective for classifying a water body is to designate uses by evaluating and describing the ecosystem. "Designated uses" are based on the relationship and quality, i.e., the integrity, of all ecosystem components. States and authorized Tribes, through their approved WQS, specify appropriate, designated uses in order to achieve and protect existing and potential uses.[14] They can select the level of specificity they desire for identifying designated uses and subcategories of uses. Subcategories of aquatic life uses may be on the basis of attainable habitat, innate differences in community structure and function, or fundamental differences in important community components. Special uses may also be designated to protect particularly unique, sensitive, or valuable aquatic species, communities or habitats.

The current state standard for listing wild rice waters is found at Minnesota Rule 7050.0224, "Specific Water Quality Standards for Class 4 Waters of the State: Agriculture and Wildlife," which at Subpart One states:

> The numeric and narrative water quality standards in this part prescribe the qualities or properties of the waters of the state that are necessary for the agriculture and wildlife designated public uses and benefits. Wild rice is an aquatic plant resource found in certain waters within the state. The harvest and use of grains from this plant serve as a food source for wildlife and humans. In recognition of the ecological importance of this resource, and in conjunction with Minnesota Indian tribes, selected wild rice waters have been specifically identified [WR] and listed in part 7050.0470, subpart 1. The quality of these waters and the aquatic habitat necessary to support the propagation and maintenance of wild rice plant species must not be materially impaired or degraded. If the standards in this part are exceeded in waters of the state that have the Class 4 designation, it is considered indicative of a polluted condition which is actually or potentially deleterious, harmful, detrimental, or injurious with respect to the designated uses.

Natural Wild Rice Waters should be classified as a distinct aquatic life use

The fundamental use in §101(a) of the Act for 'protection and propagation of fish, shellfish and wildlife' may also include the protection of aquatic flora. However, the agricultural use class (Minnesota's Class 4 waters) is intended to define *waters that are suitable for the irrigation of crops, consumption by livestock, support of vegetation for range grazing, and other uses in support of farming and ranching and protects livestock and crops from injury due to irrigation*

and other exposures.[15] The Minnesota tribes have consistently recommended to the MPCA, during multiple consultation sessions over the past three years specifically focusing on wild rice water quality standards, that natural wild rice stands (manoomin) are more appropriately classified under a distinct aquatic life use (i.e., Minnesota's Class 2 waters). It may be appropriate to leave paddy rice, a true cultivated agricultural product, in Class 4, but it is inaccurate and inherently offensive to Minnesota tribes to classify manoomin as a 'crop', and ecologically ignorant to categorize the naturally occurring hydrology of a natural wild rice bed as "irrigation." Irrigation is defined as "...to supply (dry land) with water by means of ditches, pipes, or streams."[16] This is simply not an appropriate or accurate concept for describing a native plant species growing without cultivation in a natural water body.

Wild Rice Waters listed by the Minnesota DNR and Tribes are an 'existing use'

Tribal staff have also elevated the importance of distinguishing between a "designated use" and an "existing use" in consultation with the MPCA. An "existing use" can be demonstrated by either a) that fishing/swimming has actually occurred since November 28, 1975, or b) that the water quality is suitable to allow the use to be attained--unless there are physical problems, such as substrate or flow, that prevent the use from being attained.[17] Following, "No activity is allowable under the antidegradation policy which would partially or completely eliminate any existing use *whether or not that use is designated in a State's water quality standards*. The aquatic protection use is a broad category requiring further explanation. *Non-aberrational resident species must be protected, even if not prevalent in number or importance.* Water quality should be such that it results in no mortality and no significant growth or reproductive impairment of resident species. Any lowering of water quality below this full level of protection is not allowed. A use attainability analysis or other scientific assessment should be used to determine whether the aquatic life population is in fact an artifact or is a stable population requiring water quality protection."[18]

Designated uses may be changed only based upon findings of a use attainability analysis that has demonstrated that attaining the designated use is not possible because of naturally occurring pollutant concentrations, natural flow conditions, hydrologic modifications, substantial widespread economic impact resulting from more stringent controls, or human-caused pollution that cannot be remedied. A designated use cannot be removed if the use can be attained by implementing effluent limits and best management practices.[19] Therefore, attainable uses are, at a minimum, the uses (based on the State's system of water use classification) that can be achieved: (1) when effluent limits under sections 301 (b)(l)(A) and (B) and section 306 of the

---

[15] *Id.* at Chapter 2, EPA Water Quality Standards Handbook

[16] Webster's II New College Dictionary (ISBN 0-395-70869-9) 1999. Houghton Mifflin Co.

[17] *See* Chapter 4, Water Quality Standards Handbook, *Protection of Existing Uses*

[18] *Id.*

[19] Per 40 C.F.R. Section 131.10(d), "[w]hen designating uses, States may wish to designate only the uses that are attainable. However, if the State does not designate the uses specified in section 101(a)(2) of the Act, the State must perform a use attainability analysis under section 131.10(j) of the regulation. States are encouraged to designate uses that the State believes can be attained in the future."

Act are imposed on point source dischargers; and (2) when cost-effective and reasonable best management practices are imposed on nonpoint source dischargers.

Minnesota's existing WQS require that the quality of listed and unlisted wild rice waters, and the aquatic habitat necessary to support the propagation and maintenance of wild rice plant species, not be materially impaired or degraded. In other words, Minnesota already requires the listing of *all* wild rice waters, regardless of production—the rules make no distinction based upon productivity.[20] As noted, most of the waters that now appear on MPCA, DNR, and the 1854 Treaty Authority lists *already* have an "existing use" as "waters used for the production of wild rice," whether or not they include an estimate of acres of wild rice present for any given year. These waters must remain on the wild rice waters lists for regulatory purposes. They cannot be pulled off and dropped instead onto the proposed "watch list," in effect, de-listing them as Class 4 waters of the state with the stroke of a pen. The Clean Water Act clearly states that this can only happen after significant process, including a reasoned determination has been made that production of wild rice is a designated use, not an existing use, and based upon the findings of a use attainability analysis, that the designation of "waters used for the production of wild rice" should be eliminated.

If a *designated use* is an *existing use* (as defined in 40 CFR 131.3) for a particular water body, the existing use **cannot be removed** unless a use requiring more stringent criteria is added. However, uses requiring more stringent criteria may **always be added** because doing so reflects the goal of further improvement of water quality. This is entirely consistent with the intent of not only the Clean Water Act goals, but also the intent of the DNR and Tribes in continually updating the list of wild rice waters within the state.

Productivity thresholds are not appropriate for defining wild rice waters

Even if the Act did not prohibit the watch list, it makes no sense as a conservation measure. Minnesota Chippewa Tribe Bands have consistently urged the MPCA to broadly, not narrowly, define wild rice waters, and to be as protective of this diminishing resource as possible. An unnecessarily restrictive list of "waters used for the production of wild rice" is not consistent with the principles of ecosystem management, whereby a management or regulatory agency seeks to maintain ecosystems such as wild rice waters in the appropriate condition to meet that beneficial use, while recognizing that all ecosystems have limited ability to accommodate stressors and still maintain that desired state. Using an arbitrary threshold of productivity to define "waters used for the production of wild rice" ignores the entire body of published scientific research *and* traditional ecological knowledge provided by tribal staff and tribal members that provides substantial evidence of the interannual variability in even traditionally productive waters. Given the scarcity of wild rice productivity and stand density data that the MPCA has compiled at this point in time, it is entirely premature to attempt to incorporate a representative productivity or density metric into the actual definition of a wild rice water body.

Furthermore, the Minnesota tribes with authorized water quality standards would *not* move to a less-inclusive definition or less-protective criterion even if the state adopted it. So the "watch

[20] *See* Minn. R. 7050.0224 subp. 1.

list" would also likely mean an end to an ongoing, cooperative, state-tribal conservation effort and would likely have a ripple effect on other aspects of these relationships, as wild rice is of such central importance to the Bands. As a practical matter, the result would be that the state and tribes would no longer maintain the same wild rice waters lists (at least within the 1854 Ceded Territory and on the reservations), which would undoubtedly create both administrative and permitting problems.

The "watch list" approach would have additional consequences, including delays in the environmental review process for projects with the potential to affect wild rice waters. Minnesota's wild rice waters, whether designated by the state or not, are also federally protected as tribal traditional cultural properties under Section 106 of the National Historic Preservation Act (NHPA).[21] The NHPA requires not only that a project with the potential to impact traditional cultural properties must carefully analyze potential impacts, but also stipulates that appropriate mitigation must be done or a project cannot proceed. If the same waters are not also listed at the state level, it will create a disconnect between the state and federal permitting processes and records, to the detriment of applicants, tribes, and agencies alike.

The Legislative directive can be fulfilled through MPCA's watershed-based monitoring and assessment processes

MPCA should instead continue to list all wild rice waters *regardless* of current levels of production, and should simply add productivity measurements to their assessment database as they become available over time. This is appropriately accomplished through the state's established ten-year cycle for major watershed assessments. MPCA assesses state waters through physical, chemical and biological monitoring. Biological evaluations provide a more precise statement of which species exist in a water body and therefore should be protected, determine the biological health of the water body, and determine the species that could potentially exist in the water body if the physical and chemical factors impairing a particular use were corrected. Over time, with adequate data, the MPCA should be able to make reasonably specific recommendations concerning the natural potential of a water body, levels of attainability consistent with this natural potential, confirm appropriate use designations, and identify impairments. The MPCA can most directly and appropriately address the legislative requirement for considering minimum acreage and wild rice density **through their established monitoring and assessment processes**, rather than struggling to clarify it in the definition of the wild rice designated use.

MPCA should expedite the listing of impaired wild rice waters

We also urge MPCA expedite the listing of "impaired" wild rice waters in order to ensure that water-quality-based effluent limits can be applied to discharges that exceed WQS criteria - just as Minnesota Rules already mandate. Any water body that is currently listed by the DNR, 1854 Treaty Authority, or MPCA as a wild rice water body, and is known to exceed Minnesota sulfate WQS for wild rice, should be designated as "impaired."[22] This would be consistent with the

---

[21] *See* 36 C.F.R. §§ 800 *et seq.* (2013)
[22] *See* Minn. R. 7050.0224 subp. 1.

MPCA's approach to designating any other type of impairment with assigned numeric or narrative criteria.

Conclusion

Natural stands of wild rice (manoomin) should be protected as a distinct Class 2 aquatic life use in Minnesota WQS, and the existing sulfate criteria (10 mg/l) should be maintained for this use class. Paddy rice may continue to be appropriately designated for protection under the Class 4 agricultural use. Narrowly defining waters used for the production of wild rice, based upon an arbitrary measure of human harvest potential, is inconsistent with Clean Water Act requirements. Creating a "watch list" to determine if waters already known as "wild rice waters," and listed by on the MN DNR, MPCA, or 1854 Treaty Authority, but that do not have estimated acreages, is also inconsistent with the Act. In order to protect and restore wild rice waters, natural variability in stand density and annual changes in location of stands in both streams and lakes must be acknowledged. The legislative mandate to consider wild rice acreage and stand density is most appropriately dealt with as an integral part of the MPCA's water body monitoring and assessment programs, not as a component of the water quality standard definition.

The goal should be continuing to build an inventory of natural wild rice waters that facilitates both conservation and monitoring, and that will dovetail with other procedures the MPCA is already implementing to require dischargers to do improved quality-assured monitoring. And properly listing impaired wild rice waters will ensure that water quality based effluent limits can be applied to dischargers that exceed Minnesota WQS criteria for the protection of these waters.

Sincerely,

Norman W. Deschampe

RE: Scoping Comments Regarding the Sandpiper Pipeline and Line 3 Replacement Projects, PUC Docket Numbers for Sandpiper: PL-6668/CN-13-473 and PPL-13-474; Line 3: PL-9/CN-14-916 and PPL-15-137

Dear Ms. MacAlister:

The Fond du Lac Band of Lake Superior Chippewa is a federally-recognized Indian tribe located in Northeastern Minnesota with a reservation consisting of roughly 100,000 acres. In addition to the reservation, the Band also retains usufructuary rights in an additional 9.5 million acres surrounding the reservation. These lands were ceded to the U.S. Government in the Treaties of 1837 and 1854. The Band retains all rights in the Ceded Territories that were not specifically reserved by treaty, including hunting, fishing, and gathering.

The proposed routes for both Sandpiper and Line 3 cut through the Band's Ceded Territories. The Fond du Lac Band of Lake Superior Chippewa submits the following comments regarding Enbridge's Sandpiper Pipeline and Line 3 Replacement projects.

Climate Change

Any new oil transportation infrastructure serves to encourage the country's reliance on an energy resource that is inherently damaging to the world's climate, locking us into an uncertain future for our children, grandchildren, and all future generations. The pipeline would lead to increasing greenhouse-gas emissions, killing our chances of meeting pollution-reduction targets. Continued reliance on energy from oil is altering many resources on Earth, contributing to devastating climate change.

The effects of a changing climate impact the resources on our reservation and Ceded Territories. Several species of interest to the Band are already being adversely impacted by climate change. Wild rice, for instance, is very dependent on steady water levels during the floating leaf stage. Floods on the Reservation in 2012 destroyed the wild rice crop that year. The steep decline of the moose population in northern Minnesota that has been noted over the past twelve years is believed to have been

exacerbated by hotter summers and the increased occurrence of pests. The emerald ash borer has destroyed stands of ash around the state. The health of many Native people, many of whom suffer from asthma, is worsened by mold outbreaks caused by wetter weather and higher ozone levels caused by a hotter climate. A study completed by the National Wildlife Federation ("Facing the Storm: Indian Tribes, Climate-Induced Weather Extremes, and the Future for Indian Country", 2011) details the many ways in which tribes are disproportionately impacted by climate change and the many challenges tribes face in responding to climate-related disasters.

In evaluating the no-action alternative, the DOC must consider the fact that because of the relatively easy availability of things like the tar sands oil, companies like Enbridge continue to exploit damaging energy sources rather than exploring more sustainable alternatives. Projects like this contribute to a significant loss of carbon sequestration related to the forests and wetlands that will be converted or degraded. This continues to bring us down an unsustainable path of reliance on dirty fossil fuels and more carbon emissions, while simultaneously diminishing the natural landscape's inherent resilience and the natural resource services it provides.

Instead of investing in the Sandpiper Pipeline and re-routing Line 3, the no-action alternative allows more investment in alternative energy infrastructure and promotion. Alternative energy resources like solar, wind, and water have the potential to ultimately replace our reliance on dirty oil.

1837 and 1854 treaty rights

The proposed Sandpiper route would pump 375,000 barrels per day of fracked oil across the Band's Ceded Territories. The Treaties of 1837 and 1854 promised the Band a continuation of sustenance from Reservation and Ceded Territories' water and land. Leaks and ruptures would endanger the Mississippi headwaters, Lake Superior watershed, and the wetlands that the Band relies on for our way of life.

Enbridge has a demonstrated history of negligence in pipeline safety. For instance, in 2010 in Michigan, an Enbridge pipe spilled dilbit into the Kalamazoo River, contaminating nearly forty miles of the river. It's not clear if the river will ever go back to pre-spill quality, as it is now six years after the spill and there remain lingering chemicals and crude oil in the river. In 2012, an Enbridge pipe spilled more than 50,000 gallons of light crude oil in rural Wisconsin.

Any spill from the proposed pipelines would likely render cooking, cleaning, and drinking water unusable for hundreds of years. In addition, many of the wetlands on the reservation are peat; any oil spilled into peat will continue to contaminate our resources for eons.

System Alternative

Any route alternative proposed will impact the Great Lakes, as well as the treaty-protected resources of the Band. If Enbridge is allowed to proceed with the Sandpiper and Line 3 projects, they should be required to move the system entirely away from our forest resources, wetlands, and essential water systems. The route alternative options bring pipelines through the Duluth area and create unnecessary harms to the Band's treaty resources, and to Lake Superior.

Pipeline rights-of-way (ROW) do not allow forest cover, causing fragmentation of the forest, including forested wetlands. In turn, that fragmentation disrupts the free movement of wildlife. In addition, fragmentation provides a corridor for invasive plant species to move through the area, since

most invasive plant species in this area are dependent upon full to partial sunlight provided by pipeline ROWs.

Existing pipelines on the Reservation, both active and inactive, have already negatively impacted our wetlands and forests through fragmentation and wetland degradation. The Band needs very clear assurances that our future generations are not left with an Enbridge graveyard to remember us by.

If the Band is to support a pipeline project at all, any system alternative must completely avoid the Great Lakes, not only in Minnesota but in our Ceded Territories in Wisconsin and Michigan as well. The projects should be moved to more agricultural areas of the state, where the cleanup of the anticipated spills will be easier to access and contain.

Cathodic protection and access road and locations

At numerous locations throughout any pipeline route, Enbridge will need to install cathodic protection as well as access roads. When Enbridge completed their installation of Line 67 (Alberta Clipper) and Line 13 (Southern Lights) through the Fond du Lac Reservation, they did not include any cathodic protection or access road locations in their original wetland permit application. The Band later received a separate wetland permit application for Enbridge to install cathodic protection and access roads in wetlands adjacent to MN Highway 210, essentially "piecemealing" the pipeline project. Enbridge needs to identify all locations to be impacted in their project description so that those facilities can also be properly evaluated.

Eco-system valuation

In 2015 Earth Economics published an eco-system valuation of the St. Louis River watershed, finding that

> [t]he St. Louis River watershed provides an estimated $5 billion to $14 billion in ecosystem service benefits per year which provides each of the approximately 177 thousand people living in the watershed an annual benefit of $28,248 to $79,096.
> https://www.glifwc.org/Events/Earth%20Economics%20St%20Louis%20River%20Project%20Report.pdf.

This innovative study recognizes that quantifying the value of our eco-systems gives us better tools to understand the impact that environmental decisions have on the economy as a whole.

A similar study of the eco-systems that could be impacted by the Sandpiper and Line 3 projects should be done by an independent third party, such as the Great Lakes Indian Fish & Wildlife Commission.

Financial assurances

Enbridge must be held responsible for any oil spill that might happen from its pipelines. Before the company is allowed to take on these projects, it should be required to provide evidence of financial assurance, such as insurance or alternative financial security, which covers the full cost of recovery from any disaster which could happen as a result of the presence of its pipelines. The cost should be evaluated using an eco-system valuation study as discussed in the previous section. Enbridge must show that it has

the resources to cover the full costs of pollution damage as well as both remediation and restoration costs incurred by public and tribal agencies in preventing and cleaning up any spill that could happen.

Enbridge's purpose and need for this project is based on the assumption that the global economy will need more oil. This assumption is not well-founded, given recent international commitments to reduce carbon emissions as well as recent plunges in global oil markets. The DOC should fully analyze the no-build, no-replacement alternative, including a full quantification carbon impacts.

The Band looks forward to continued consultation on these issues.

Sincerely,

RE: Scoping Comments Regarding the Sandpiper Pipeline Project and the Line 3 Replacement Pipeline Project, PUC Docket Numbers for Sandpiper: PL-6668/CN-13-473 and PPL-13-474; Line 3: PL-9/CN-14-916 and PPL-15-137

Dear Ms. MacAlister:

The Sandpiper Route Alternative-37 (RA-37), which would traverse through the southern edge of the external boundary of the Fond du Lac Reservation, has been reviewed pursuant to the responsibilities given to the Fond du Lac Tribal Historic Preservation Office (THPO) by the National Historic Preservation Act (NHPA) of 1966 and the Procedures of the Advisory Council on Historic Preservation (36CFR800).

A spatial/graphic review of Fond du Lac's Cultural Resources Inventory identified that RA–37 would traverse within Fond du Lac's Cultural Preservation Zone that includes significant cultural/natural resources that provide a water source and several wild rice waters that the Band depends upon. Wild rice is basic to the traditional diet and important both culturally and spiritually as well as a central element in feasts and ceremonies. The quality of these waters and the aquatic habitat is essentially important to Band members.

From a cultural perspective, in recognition of the ecological importance of key cultural/natural resources within the external boundary of the Reservation, our concerns in regard to RA-37 footprint from both direct and indirect damage potential are substantial.

The Fond du Lac Band of Lake Superior Chippewa strongly requests that the Route Alternative RA-37 be omitted from the EIS Scoping Decision Document and no further analysis of this alternative be conducted.

The Band looks forward to continued coordination and consultation on this issue.

Sincerely,

Wally Dupuis

The National Congress of American Indians
Resolution #MSP-15-040

TITLE: Calling for Environmental Justice and a Full Environmental Impact Statement on Enbridge Energy's Proposed Tar-Sands Oil Pipeline Across Treaty-Ceded Territory in Minnesota

WHEREAS, we, the members of the National Congress of American Indians of the United States, invoking the divine blessing of the Creator upon our efforts and purposes, in order to preserve for ourselves and our descendants the inherent sovereign rights of our Indian nations, rights secured under Indian treaties and agreements with the United States, and all other rights and benefits to which we are entitled under the laws and Constitution of the United States, to enlighten the public toward a better understanding of the Indian people, to preserve Indian cultural values, and otherwise promote the health, safety and welfare of the Indian people, do hereby establish and submit the following resolution; and

WHEREAS, the National Congress of American Indians (NCAI) was established in 1944 and is the oldest and largest national organization of American Indian and Alaska Native tribal governments; and

WHEREAS, Manoomin, or Wild Rice, is a sacred food to the Anishinaabe of tremendous spiritual and cultural importance, a federally-protected tribal resource, and tribal harvesters in Minnesota are the largest producers of hand-harvested wild rice in the United States; and

WHEREAS, tribal governments throughout Minnesota and Wisconsin have significant concerns that the development of, and any release from, Enbridge Corporation's Sandpiper oil pipeline along its proposed route would have devastating impacts on unique spiritual and cultural resources, as the proposed pipeline route will cross directly through the most sensitive wild-rice producing lakes and rivers within the treaty-ceded territories in Minnesota; and

WHEREAS, over tribal objections, the Minnesota Public Utilities Commission (MPUC) rescheduled its determination meeting to a date two weeks earlier than the notice provided to tribes, and no testimony from the tribes' own hearings could be entered into the MPUC record; and

WHEREAS, the MPUC issued a project determination of need approval on June 5, 2015, without any tribal consultation, consideration of testimony, investigation of impacts to tribal resources, or environmental justice issues—raising the concern that future approvals will issue in a similarly perfunctory manner; and

WHEREAS, Enbridge has begun initial consultation with the U.S. Army Corps of Engineers regarding Section 404 Permits for the project, and the U.S. Environmental Protection Agency (EPA) will perform, at least, a consulting role under Section 106 of the National Historic Preservation Act and oversight on the Army Corps' environmental impact statement, pursuant to Section 309 of the Clean Air Act.

NOW THEREFORE BE IT RESOLVED, that the NCAI calls upon EPA to engage with the Army Corps immediately to stress concerns and advocate for the most thorough environmental review possible, including respect of tribal resources and environmental justice issues; and

BE IT FURTHER RESOLVED, that EPA must assist the appropriate Bands of Chippewa/Ojibwe to become designated as "cooperating agencies" during NEPA review; and

BE IT FURTHER RESOLVED, that EPA urge that a joint Federal-State Environmental Impact Statement be undertaken to enhance coordination around novel and complex tribal resource and environmental issues; and

BE IT FURTHER RESOLVED, that NCAI requests that EPA investigate whether the pipeline requires other federal environmental permits that fall within the agency's direct jurisdiction; require a jurisdictional determination be made by Army Corps; designate a high-level EPA official as a liaison to tribal governments on all aspects of the Sandpiper project; and meet with the affected tribes and bands following issuance of the recommendations from the June 5, 2015, hearing on the Sandpiper pipeline; and

BE IT FINALLY RESOLVED, that this resolution shall be the policy of NCAI until it is withdrawn or modified by subsequent resolution.

CERTIFICATION

The foregoing resolution was adopted by the General Assembly at the 2015 Midyear Session of the National Congress of American Indians, held at the St. Paul River Centre, St. Paul, MN, June 28 to July 1, 2015, with a quorum present.

Brian Cladoosby, President

ATTEST:

Aaron Payment, Recording Secretary

RESOLUTION 72-17

WHEREAS, the Minnesota Chippewa Tribal Executive Committee is the duly elected governing body of the Minnesota Chippewa Tribe (MCT), comprised of six member reservations (Bois Forte, Fond du Lac, Grand Portage, Leech Lake, Mille Lacs and White Earth), each of which is separately recognized by the United States as an Indian tribe; and

WHEREAS, the Revised Constitution and Bylaws of the Minnesota Chippewa Tribe provides that the purposes of the tribal organization under the Act of June 18, 1934 (48 Stat. 984) include the conservation of tribal resources and promotion of the general welfare of members of the Tribe; and

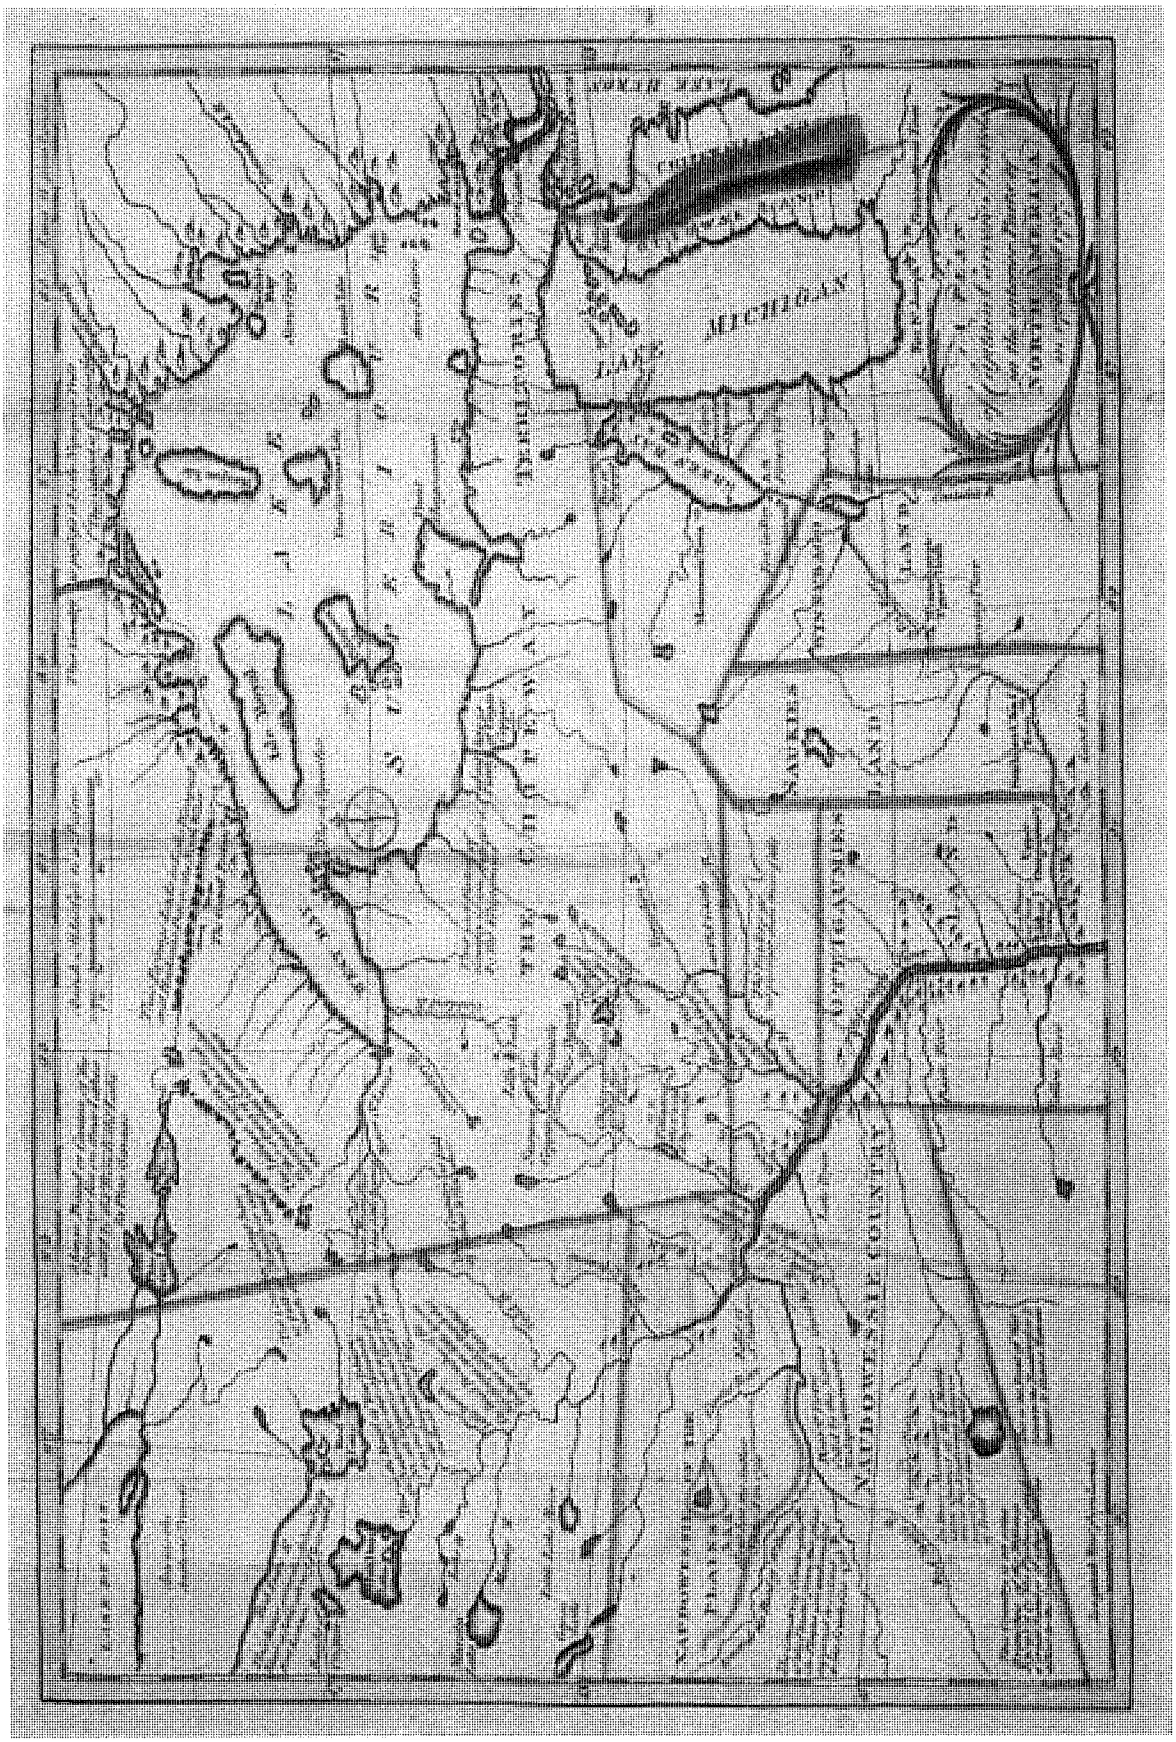
WHEREAS, water sustains all life, and the protection of clean water is high on our list of sacred responsibilities as Anishinabe people; and

WHEREAS, because manoomin, or wild rice, is also sacred to Anishinabe people, it has been recognized by the federal government as a trust resource with protections to guarantee its survival; and

WHEREAS, because all surface waters and ground waters are interconnected, even subtle changes in water quality or levels can profoundly harm the health of manoomin; and

WHEREAS, private companies have been planning several oil pipelines, underground and strip mines, and other large infrastructure projects that will cross and/or impact lands and waters where Tribal members gather wild rice and other natural resources, and where Tribal cultural resources are located; and

WHEREAS, construction of large infrastructure and large energy projects pose substantial threats to waters, natural resources and important cultural resources from disturbance during construction and permanent environmental destruction through ongoing project activities; and



WHEREAS, it is now essential for the MCT to conduct a tribal cumulative impacts analysis with input and collaboration among the MCT Bands that may be incorporated into the administrative record of an EIS to preserve legal arguments and standing; and to also serve as substantive, relevant comments for any future proposed large infrastructure project that may impact reservations, treaty lands or treaty-protected resources; and

BE IT FURTHER RESOLVED, that the Tribal Executive Committee hereby directs that such *tribal cumulative impacts assessment* be initiated immediately to allow Bands to identify tribal natural and cultural resources that may be impacted by the large infrastructure projects; and

We do hereby certify that the foregoing Resolution was duly presented and acted upon by a vote of 8 For, 1 Against, 1 Silent, at a Special Meeting of the Minnesota Chippewa Tribal Executive Committee, a quorum present, held on March 15, 2017 at Hinckley, Minnesota.

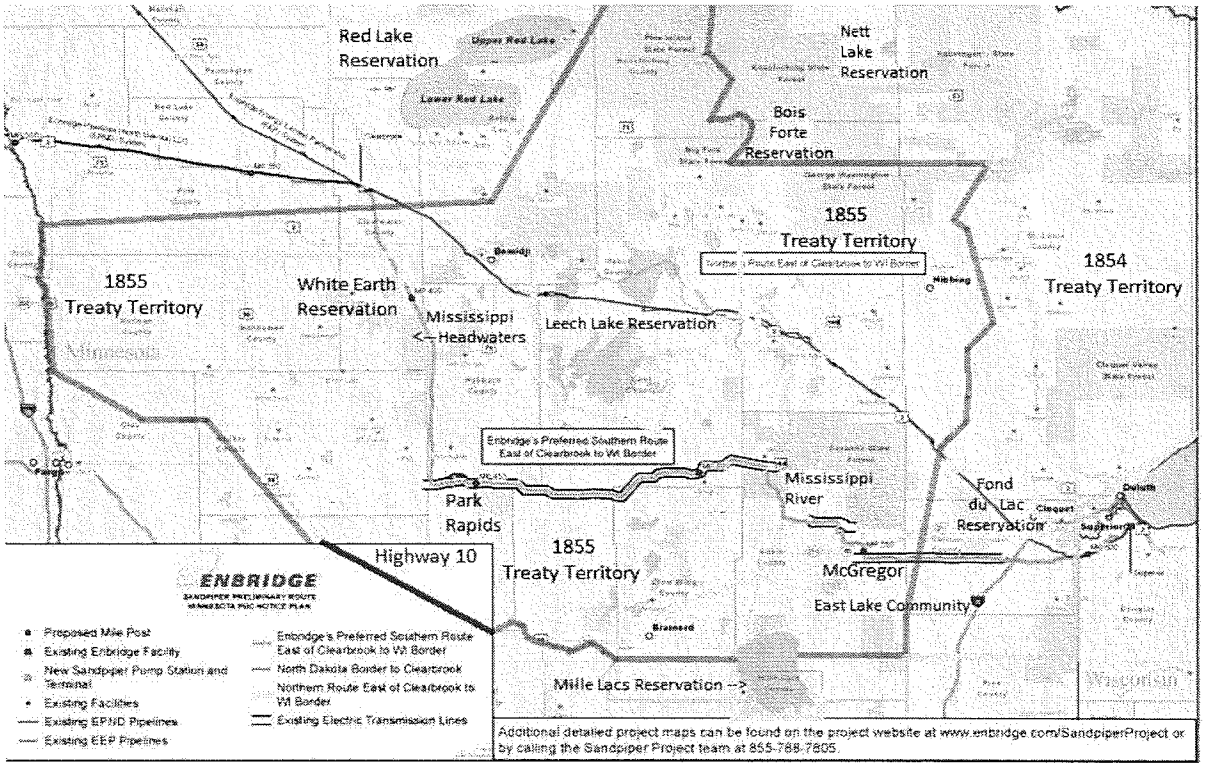
Re: Guidance on how federal agencies can better ensure meaningful tribal input into infrastructure-related reviews and decisions
AND
Minnesota Chippewa Tribe environmental protection
Resolutions 30-17 and 32-17

Dear Administrators:

Please accept this letter along with the two (2) Minnesota Chippewa Tribe Resolutions adopted last month as tribal input for the 2016 consultation period that just concluded. We share your understanding the tribal nations voices must be



heard with regard to federal decisions that will affect our treaties, homelands, environment, cultural properties, and sacred sites. The two (2) MCT resolutions provide tribal guidance on how federal agencies can better ensure meaningful tribal input into infrastructure-related reviews and decisions, to protect tribal lands, resources, and treaty rights within the existing statutory framework.

Additionally, the MCT Resolutions request federal coordination with US Army Corps of Engineers to develop new Clean Water Act Section 404 permitting processes for wild rice waters in recognition of the special impacts created to wild rice resources, and to condition 404 permit approval over infrastructure projects occurring within tribal aboriginal lands with serious potential impacts to tribal cultural and natural resources on receipt of the informed consent of the impacted tribes, and that the US Army Corps of Engineers:

> (1) consult with the Minnesota Chippewa Tribe and its constituent Bands to update the guidelines (Exhibit A);
> (2) make a firm unequivocal commitment that it will follow those guidelines and fulfill its trust obligations to Indian tribes; and
> (3) enter into agreements with the MCT or a constituent Band to establish protocols for tribal input and consultation on proposed actions impacting tribal cultural and natural resources.

The 1855 Treaty Authority is comprised of approximately 30,000 tribal members of the 40,000 enrolled members of the MCT. The majority of the environmental impacts from the proposed Line 3 Pipeline project will occur within the 1855 ceded territory by (1) establishing a new, east-west pipeline corridor where none previously exists, crossing new aquifers and wild rice lakes and rivers, and (2) by abandoning many miles of pipeline in the Mainline corridor of previously compromised wild rice lakes and rivers and aquifers. The Enbridge Sandpiper pipeline map has been modified to identify the 1855 and 1854 ceded territories and

Minnesota Chippewa reservations and is the same preferred corridor for Enbridge's Line 3 Replacement route.

The concerns and goals represented in the two MCT Resolutions identify the same problem areas facing all of *Indian Country* and ultimately resulting in the Dakota Access pipeline standoff; (1) States acting as though states can unilaterally risk important environmental and cultural tribal resources, and (2) the United States Army Corps of Engineers failing to fulfill trust responsibility described under the 1997 Issue Paper. (See Exhibit A attached to MCT Res. 32-17).

We believe it is important to work with the DOI, BIA, DOJ, EPA and USACE to develop a 2017 Issue Paper to provide guidance for all the federal agencies and states for tribal consultation. While the MCT EIS (Res. 30-17) process is important for self-governance and environmental protection, it will best be

accomplished in a new cooperative model with the aforementioned federal agencies. A good place to start is with the EIS how to identify our necessary and important cultural resources while recognizing the number one global threat identified by the Department of Defense is climate change and will necessarily require a full cycle environmental analysis as described by the EPA. The MCTEIS Coordinator is Michael Northbird and may be reached at 218-335-8581, ext. 128 and mnorthbird@mnchippewatribe.org Meetings regarding the preparation of the MCT EIS and public notices for upcoming information sessions to take comments or other hearings are scheduled in the near future, starting with Leech Lake Reservation on January 4, 2017.

We look forward to hearing back from you in the near future about upgrading the 1997 Issue Paper with regard to Chippewa treaty rights and developing a broader tribal guidance paper of how the Corps of Engineers may better carry out its trust responsibilities.

If you have any questions, or if I may be of further assistance, please call on me at 218-760-1258 or via email at frankbibeau@gmail.com. Mii gwitch.

Best wishes,

/s/ Frank Bibeau

Line 3 Replacement Project: Assessment of Accidental Releases: Technical Report

Prepared for:
Department of Commerce, Energy
Environmental Review Analysis Staff

Prepared by:
Stantec Consulting Services Inc.
RPS/ASA
Dynamic Risk Assessment Systems Inc.

January 13, 2017

PREFACE

Stantec Consulting Ltd. (Stantec), RPS Group PLC (RPS), and Dynamic Risk Assessment Systems, Inc. (Dynamic Risk) were retained to prepare a risk assessment for potential large releases of crude oil from the Line 3 Replacement Project (L3RP).

PURPOSE

The purpose of this document is to provide information on the risk of an accidental large volume release of crude oil from the proposed L3RP at seven individual watercourse crossing sites. These seven sites were selected to be representative of the broad geographic and environmental diversity, including environmentally sensitive areas, that are: (1) present throughout the State of Minnesota; and (2) intersected by both the preferred and alternative L3RP routes.

Risk is defined most concisely as the 'chance of loss'. Accordingly, in the context of the risk associated with the operation of the L3RP pipeline, the term 'risk' is used as a joint expression of chance (the annual probability of incurring a rupture in the L3RP pipeline) and loss (the consequences associated with such a rupture).

As stated in the Final Scoping Decision Document for Line 3 Pipeline Replacement Project, the risk assessment was conducted to assess potential effects (i.e., consequences) associated with an accidental large volume release of crude oil using computational modeling to investigate releases at seven individual representative sites throughout north and central Minnesota. Information from the modeling of large crude oil releases at these representative sites will be used to make broad assessments of the potential consequences that are predicted across a range of geographic and environmental regions. Results can be used to make comparisons between similar environments to understand the potential effects that may occur at other locations with similar features among and across all proposed or alternative routes.

DIRECTION ON TECHNICAL WORK

Stantec, RPS and Dynamic Risk (referred to collectively as the Consulting Team) were retained by Enbridge Energy, Limited Partnership (Enbridge). The Consulting Team was responsible for identifying potential approaches for assessing the risk (as both failure likelihood/probability and potential consequences) of large crude oil releases, and identifying a preferred approach based on comments from the Minnesota Department of Commerce, Energy Environmental Review and Analysis (DOC-EERA) (including state and federal agencies and their consultant) and Enbridge. Once the preferred approach was identified, the Consulting Team undertook the technical work under its own direction. Presentations on the preliminary results of the technical work were made to the DOC-EERA, state and federal agencies, and Enbridge at several points during the completion of the technical work. Every party was involved in each phase of the

work, including formulating the questions, identifying an approach, specifying the model inputs, assessing the outputs, and discussing the conclusions.

The Consulting Team then prepared a technical report on the risk assessment, with the exception of Chapter 2: Project Description, which was prepared by Enbridge. Comments on the draft report were received from the DOC-EERA and Enbridge. In response to these comments, revisions to the draft report were undertaken by the Consulting Team, but only where the Consulting Team deemed the changes to be appropriate. The work's technical conclusions were unchanged by the revisions accepted. A final report was prepared by the Consulting Team for submission to the DOC-EERA.

FUNDING

Funding for the work undertaken by the Consulting Team was provided by Enbridge.

AUTHORSHIP

The risk assessment of large releases of crude oil was prepared by the Consulting Team. The Technical Lead for each section of the report was as follows:

Chapter	***Technical Lead(s) Responsible for the Chapter***
1.0 INTRODUCTION	Jeff Green, Stantec
2.0 PROJECT DESCRIPTION	Enbridge Application
3.0 FRAMING THE SITE SELECTION AND MODELING ANALYSIS	Jeff Green, Stantec and Matt Horn, RPS
4.0 FAILURE PROBABILITY ANALYSES	Jim Mihell, Dynamic Risk
5.0 MODELING OF OIL RELEASES	Matt Horn, RPS
6.0 TRAJECTORY AND FATE RESULTS FOR MODELING LOCATIONS	Matt Horn, RPS
7.0 ASSESSMENT OF ENVIRONMENTAL EFFECTS OF OIL RELEASES	Malcolm Stephenson, Stantec
8.0 REVIEW OF ENVIRONMENTAL RECOVERY FOLLOWING RELEASES OF OIL	Heidi Tillquist, Stantec
9.0 SUMMARY AND CONCLUSIONS	Consulting Team
10.0 REFERENCES	Consulting Team

DECLARATION

As the Technical Leads for the Risk Assessment of Large Releases of Oil for the Line 3 Replacement Project, we verify that we are responsible for leading and managing the preparation of the chapters of the report, as described in the above table. All technical analyses and all conclusions reflect our work and opinions. Modifications in response to verbal or written comments from the DOC-EERA, state and federal agencies or Enbridge have not modified the technical aspects and results of our work or our conclusions.

Jeff Green, Stantec

7.0 ASSESSMENT OF ENVIRONMENTAL EFFECTS OF OIL RELEASES 7.349
7.1 REVIEW OF OBSERVED AND EXPECTED EFFECTS OF OIL RELEASES ON KEY ECOLOGICAL AND HUMAN RECEPTORS 7.353
7.1.1 Fate of Oils Released to Freshwater Environments 7.353
7.1.2 Land Cover Receptors 7.363
7.1.3 Biological Receptors 7.475
7.1.4 Human Receptors 7.575
7.2 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL NEAR MOSQUITO CREEK 7.594
7.2.1 Description of the Freshwater Environment 7.594
7.2.2 High Consequence Area Assessment for the Mosquito Creek to Lower Rice Lake Scenario 7.598
7.2.3 Selection of Key Ecological and Human Environment Receptors for Mosquito Creek to Lower Rice Lake Scenario 7.600
7.2.4 Modeled Conditions at the Release Location 7.602
7.2.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.604
7.2.6 Qualitative EHHRA for the Mosquito Creek to Lower Rice Lake Scenario 7.608
7.3 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE MISSISSIPPI RIVER AT BALL CLUB 7.623
7.3.1 Description of the Freshwater Environment 7.623
7.3.2 High Consequence Area Assessment for the Mississippi River near Ball Club Crossing Location 7.627
7.3.3 Selection of Key Ecological and Human Environment Receptors for Mississippi River near Ball Club Crossing Location 7.629
7.3.4 Modeled Conditions at the Release Location 7.631

7.3.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.633
7.3.6 Qualitative EHHRA for the Mississippi River near Ball Club 7.640
7.4 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL AT THE SANDY RIVER CROSSING 7.656
7.4.1 Description of the Freshwater Environment 7.656
7.4.2 High Consequence Area Assessment for the Sandy River, MN 7.660
7.4.3 Selection of Key Ecological and Human Environment Receptors for Sandy River 7.663
7.4.4 Modeled Conditions at the Release Location 7.665
7.4.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.666
7.4.6 Qualitative EHHRA for the Sandy River 7.671
7.5 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE SHELL RIVER CROSSING AT TWIN LAKES, MN 7.685
7.5.1 Description of the Freshwater Environment 7.685
7.5.2 High Consequence Area Assessment for the Shell River at Twin Lakes, MN 7.689
7.5.3 Selection of Key Ecological and Human Environment Receptors for Shell River at Twin Lakes 7.691
7.5.4 Modeled Conditions at the Release Location 7.693
7.5.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.695
7.5.6 Qualitative EHHRA for the Shell River at Twin Lakes 7.700
7.6 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE RED RIVER 7.716
7.6.1 Description of the Freshwater Environment 7.716
7.6.2 High Consequence Area Assessment for the Red River 7.720
7.6.3 Selection of Key Ecological and Human Environment Receptors for Red River 7.722
7.6.4 Modeled Conditions at the Release Location 7.723
7.6.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.725
7.6.6 Qualitative EHHRA for the Red River 7.730
7.7 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE MISSISSIPPI RIVER AT PALISADE 7.743
7.7.1 Description of the Freshwater Environment 7.743
7.7.2 High Consequence Area Assessment for the Mississippi River near Palisade Crossing Location 7.747
7.7.3 Selection of Key Ecological and Human Environment Receptors for Mississippi River near Palisade Crossing Location 7.750
7.7.4 Modeled Conditions at the Release Location 7.751
7.7.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.753

7.7.6 Qualitative EHHRA for the Mississippi River near Palisade 7.759
7.8 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE MISSISSIPPI RIVER AT LITTLE FALLS 7.774
7.8.1 Description of the Freshwater Environment 7.774
7.8.2 High Consequence Area Assessment for the Mississippi River near Little Falls Crossing Location 7.778
7.8.3 Selection of Key Ecological and Human Environment Receptors for Mississippi River near Little Falls Crossing Location 7.781
7.8.4 Modeled Conditions at the Release Location 7.782
7.8.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils 7.784
7.8.6 Qualitative EHHRA for the Mississippi River near Little Falls 7.791

Glossary

Actinomycetes: bacteria that resemble fungi because their elongated cells form long filaments or hyphae.

Aquatic Benthic Macroinvertebrates: Invertebrates that spend at least some portion of their life cycle in an aquatic habitat, that live in or on the bottom substrate and that are large enough to be seen without magnification.

Automatic Ultrasonic Testing (AUT) Phased Array Inspection: An advanced ultrasonic testing process in which timed pulsed ultrasonic signals from an array of ultrasonic transducers are swept through a range of angles, and subsequently analyzed by a computer algorithm to identify and size defects that might reside in a weld.

Biophysical Environment: The biotic (living) and abiotic (non-living) surroundings.

Biosparging: Compressed air injected at low flow rates below the water table used to increase dissolved oxygen levels in the groundwater to enhance biodegradation.

Bioventing: Ambient air injected or extracted at low flow rates and used to replenish oxygen for microbial respiration in the vadose zone.

Clean up: collection and removal of oil from the environment.

Direct Current Voltage Gradient (DCVG): An above-ground electrical survey technique used for assessing the effectiveness of corrosion protection and for locating coating faults on buried steel pipelines.

Dissolution: Water soluble compounds in oil dissolve into surrounding water.

Double Submerged Arc Welded (DSAW) steel line pipe: Steel line pipe manufactured from skelp that is formed into a tubular shape, and in which the seam is welded using the double submerged arc welding process.

Ectomycorrhizae: mycorrhizal fungi with a sheath that forms around the root tips of a plant and hyphae that penetrate into the root structure.

Electric Resistance Welded (ERW) steel line pipe: Steel line pipe manufactured from skelp that is formed into a tubular shape, and in which the seam is welded using the electric resistance welding process.

Emulsification: Combination of two liquids with one being suspended in the other.

Fish Kill: A significant and sudden death of fish, shellfish and other aquatic animals. Such events are characterized by large numbers of animals dying over a short time, usually in a defined area.

Gas Metal Arc Welding (GMAW): A welding process that utilizes an electric arc to fuse both the base metal and a consumable wire, both of which are shielded by an inert gas to prevent undesirable reaction of atmospheric gases with the molten metal that is formed during the welding process.

Groundwater: Water below the earth's surface that occurs below the water table in the soil pores and bedrock fractures.

Hard Spot: Associated with vintage pipe manufacturing processes, hard spots are local changes in hardness of steel pipe resulting from non-uniform quenching procedures during manufacture, or changes in chemistry of the steel. Hard spots, when stressed, are subject to failure from mechanisms such as hydrogen-stress cracking.

Hardenability: The characteristic of steel, related to its chemical constituents, which enables it to become hard when subjected to heat treatment, such as heating and quenching, or welding.

High Strength Low Alloy (HSLA): A type of steel alloy steel that provides superior mechanical properties and weldability through the use of small additions of micro-alloy elements such as niobium and / or vanadium along with thermal-mechanical controlled processing.

Horizontal Directional Drilling (HDD): A steerable trenchless method of installing underground pipe in an arc along a prescribed bore path by using a surface-launched drilling rig, with minimal impact on the surrounding area.

Hydrostatic testing: Hydrostatic testing is a process of verifying the integrity of the pipeline before it is placed into service. Hydrostatic testing involves filling the pipeline with water to a designated pressure and holding it for a specified period of time.

In situ: in place or on site.

Internal Coupon: A metal strip that can be inserted at strategic locations within a pipeline and subsequently retrieved and evaluated at periodic intervals to monitor corrosion during the operation of a pipeline.

Monte Carlo Analysis: A computer-based technique that employs stochastic resampling of randomly-selected variables from probability density functions representing the distribution of those variables. In reliability analysis, the selection of each unique combination of random variables is used to establish whether a limiting condition has been exceeded. By iterating this analysis numerous times, the fraction of times that the limiting condition is exceeded can be estimated with a degree of confidence that is related to the number of iterations used in the analysis.

Lentic: Still waters such as lakes and ponds.

Lotic: Flowing waters such as rivers, streams and brooks.

Macrophytes: Aquatic plants large enough to be visible with the naked eye.

Mycelium: vegetative part of a fungus consisting of the hyphae (branching filaments).

Natural Attenuation: A variety of physical, chemical, or biological processes that, under favorable conditions, act without human intervention to reduce the mass, toxicity, mobility, volume, or concentration of contaminants in soil or groundwater. These in situ processes include biodegradation; dispersion; dilution; sorption; volatilization; radioactive decay; and chemical or biological stabilization, transformation, or destruction of contaminants (from USEPA).

Phytoremediation: use of plants to clean contaminated sites.

Photo-oxidation: The degradation of oil by sunlight that results in the loss of alkylated polycyclic aromatic hydrocarbons.

Photolysis: Process whereby molecules are broken down into smaller units by the absorption of light.

Phytotoxic: harmful or lethal to plants.

Reclamation: return of areas disturbed by cleanup activities to approximate pre-disturbance conditions through reseeding and other methods.

Recovery: Return of an ecosystem or Valued Ecosystem Component to some desired state following disturbance.

Remediation: physical chemical or biological processes applied post cleanup to reduce contaminant concentrations.

Rehabilitation: the transfer of oiled wildlife to specialized treatment to clean up the oil and return the specimen to health.

Restoration: Taking action to return natural resources to pre-spill conditions (from USFWS). Rehabilitating, replacing, or acquiring the equivalent of injured natural resources and the services they provided. Restoration includes both primary and compensatory restoration projects (from NOAA). Physical alterations of habitat and environmental structures to restore the habitat.

Riffle Habitat: Lotic habitat of shallow fast flowing turbulent water.

Rhizome: horizontal underground stem able to produce roots and shoots.

Silt fence: A silt fence is a sediment control device used on construction sites to protect nearby wetlands and waterbodies from stormwater runoff. A typical fence consists of a piece of synthetic fabric (sometimes referred to as geotextile fabric) stretched between a series of stakes where runoff is expected to reach wetlands or waterbodies. The fabric filters remove sediment from the water before it reaches the wetland or waterbody.

Skelp: Steel that is rolled into plate form so that it can subsequently be formed and welded into pipe.

Slope breaker: A slope breaker is an erosion control device to reduce stormwater runoff velocity and divert it from the disturbed construction area to more stable ground. A typical slope breaker consists of a ridge or channel constructed diagonally across the right-of-way on a hill.

Sorption: Removal of solutes from solution onto mineral surfaces.

Specified Minimum Yield Strength (SMYS): The specified minimum stress that a material can be subjected to before it experiences permanent deformation.

Temperate Zone: In the Northern Hemisphere, the area between the tropic of Cancer and the Arctic Circle.

Thermomechanical Controlled Processing (TMCP): A steelmaking technique that utilizes carefully-designed hot-reduction and cooling schedules, typically in conjunction with micro-alloying with elements such as niobium and / or vanadium, along with other elements in order to achieve superior mechanical properties and weldability.

Transmissivity: Ability of a formation to transmit oil to a recovery well.

U & O Expansion (UOE) steel line pipe: Steel line pipe manufactured from skelp that is formed into a tubular shape by first forming a U-shape, and subsequently forming a cylinder with a longitudinal seam, which is then sealed by welding.

Vadose zone: Region of aeration above the water table, including the capillary fringe.

Volatilization: Vapors from volatile components of the oil disperse into the soil gas above the water table and diffuse laterally and upwards.

Weldability: The ease with which welding of a given material can be performed without producing defects such as cracks due to undesirably high hardenability (See also Hardenability).

1.0 INTRODUCTION

Stantec Consulting Services Inc. (Stantec), RPS Group PLC (RPS), and Dynamic Risk Assessment Systems, Inc. (Dynamic Risk) (referred to collectively as the Consulting Team) were retained to prepare a risk assessment for potential large releases of oil from the Line 3 Replacement Project (L3RP). The proposed preferred route for the L3RP is provided in Figure 1-1.

1.1 BACKGROUND ON L3RP

Enbridge Energy, Limited Partnership (Enbridge) is proposing the L3RP to replace Enbridge's existing Line 3 pipeline, from the Joliette Valve in Pembina County, North Dakota to Clearbrook, Minnesota, and then on to an existing terminal in Superior, Wisconsin (Figure 1-1).

The L3RP route is approximately 363 miles long, 337 of which are in Minnesota. The remainder of the pipeline is located in North Dakota and a small portion in Wisconsin. Within Minnesota, L3RP would involve the construction and operation of a 36-inch diameter, underground crude oil pipeline. The Project would also include a new pump station and improvements at the existing Clearbrook Terminal, the expansion of three other existing pump stations west of Clearbrook, and the addition of four new pump stations in Minnesota east of Clearbrook.

The replacement pipeline will be co-located with the existing Line 3 and Enbridge's Mainline Corridor from the Minnesota/North Dakota border to Clearbrook. This portion of L3RP would be parallel to and approximately 25 feet (ft) from the existing Line 67 pipeline. For the remaining 246 miles of the L3RP route south and east of Clearbrook, the pipeline would be located in a new right-of-way (ROW), portions of which will parallel other existing third-party pipelines, electric transmission corridors, and transportation corridors.

L3RP would transport a variety of crude oils that range from light to heavier crude oils, including diluted bitumen.

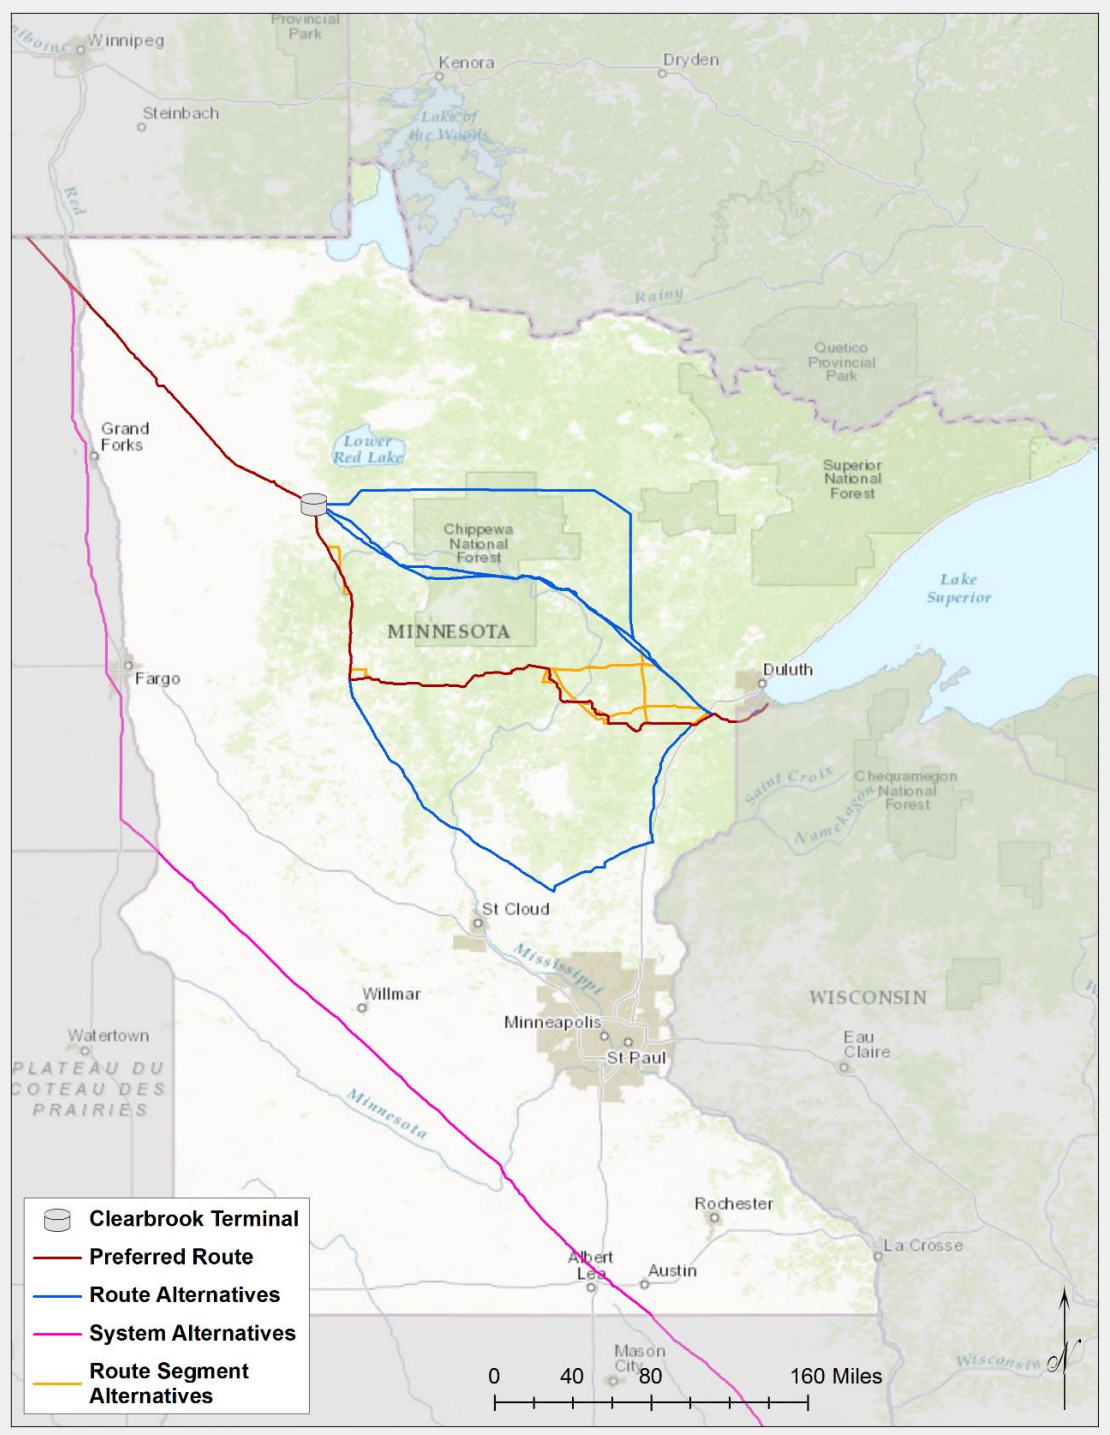

Figure 1-1 Map of the Preferred Route for L3RP, Route Alternatives, Route Segment Alternatives and System Alternatives

1.2 SCOPE OF THE ASSESSMENT

The Final Scoping Decision Document (FSDD) for L3RP (Minnesota DOC-EERA 2016) describes the topics that need to be addressed in the Environmental Impact Statement (EIS) to be prepared by the Minnesota Department of Commerce, Energy Environmental Review and Analysis (DOC-EERA).

In regard to the analysis of large oil releases, the EIS is to include "spill modeling and a summary and application of analysis methods from other projects." The FSDD states that the Applicant (Enbridge) will provide "data on maximum spill volumes, spill frequency, and the types of crude oil to be transported based on the proposed engineering and operations for the pipeline". This information will be applied to all large-volume spill impact analysis methods. An estimated large-volume spill footprint will be established using these data and based on methods used by other current or recent investigations. The methods will consider general geomorphic conditions in Minnesota to develop a general spill footprint. The analysis will also include a review of crude oil release data from the Pipeline and Hazardous Materials Safety Administration (PHMSA) database."

In addition, the FSDD states that "to assess potential impacts associated with an accidental release, the Applicant will provide maximum spill volume estimates based on response times, valve locations, and pipeline volumes at seven representative sites assuming a complete pipeline rupture. Data generated from modeling at representative sites will be used to make broad environmental comparisons among and across routes in areas with similar features." Modeling will include "a set of scenarios that include the following crude oil types: light sweet Bakken crude oil, Cold Lake Blend (CLB), and Cold Lake Winter Blend (CLWB). These crude oils represent the range of oil densities and chemical compositions expected. Additional modeling parameters include seasonal variation to capture water flow volumes (high flow, low flow, and snow/ice covered), and a 24-hour model run with outputs at 6, 12, and 24 hours. The combinations of model inputs will result in more than 40 modeling scenarios from which to analyze potential impacts to resources along route alternatives."

1.3 PURPOSE

The purpose of this document is to provide information on the risk of a large volume release of crude oil from the proposed L3RP. Risk is defined most concisely as the "chance of loss". Accordingly, in the context of the risk associated with the operation of the L3RP pipeline, the term "risk" is used as a joint expression of chance (the annual probability of incurring a rupture in the L3RP pipeline), and loss (the consequences associated with such a rupture).

For an oil release, there are several probabilities that should be considered in a risk assessment:

- Probability that a release will occur (i.e., failure frequency)
- Probability that any released oil will reach an environmentally sensitive area or receptor (modeling helps to understand spatial and temporal behavior of oil releases)

- Probability that environmentally sensitive and vulnerable species will be present or a human use will occur in the area affected by a release during the period in which there is a possibility of exposure to oil (i.e., knowing how an oil release behaves in space and time provides a better understanding of how an environmental component might be exposed to the release and what the environmental effects might be if a spill occurred)

To address the probability of large volume releases of crude oil, as well as the likely consequences associated with large volume releases of crude oil release if it were to occur, a number of factors and aspects are considered in this report, including:

- Probability that a large release of oil will occur, including an assessment of natural and human-caused threats to the pipeline, an assessment of the likelihood of a specific type of threat resulting in a large oil release (i.e., failure frequency), and the corresponding reasonable worst-case volume of oil released
- Modeling hypothetical large releases of several types of crude oil in terrestrial and freshwater environments to understand the fate of potential large oil releases with respect to the likely trajectory from specific release locations and the potential behavior of the oil within the environment, taking into account the geographic and environmental conditions where the modeled release occurs, including seasonal variability in the conditions
- Based on the results of the oil release modeling, assessment of the resources that may be affected and the range of potential effects that may result, should a large release of oil occur in the natural (physical and biological) and human environment[1]
- Potential for the natural and human environment to recover from the effects of a large oil release following the event, including a discussion of factors that can promote or impair recovery and the approximate timing of recovery

Each of these topics is discussed in the corresponding chapters of this report (see Section 1.4 for a discussion of the report structure and content).

Other topics of relevance to understanding the potential for, and management of, accidental releases of crude oil include:

- Understanding how the likelihood of an oil release can be reduced through pipeline design, construction techniques, technical specifications, operational protocols, ongoing monitoring, inspection, and maintenance
- Preparation of emergency response plans, including the incident command structure, internal communications, and ongoing commitments by the project proponent, Enbridge, and government agencies for preparedness of personnel and equipment, training, and regular exercises and drills
- Development of measures to reduce and manage the physical spread of hydrocarbons if a release occurs
- Range of measures that would be employed by Enbridge to clean up and rehabilitate areas affected by an oil release

[1] The natural environment includes the atmospheric environment, ground water and surface water, terrain, soils, freshwater fish, vegetation, wetlands, and wildlife, including rare and endangered species. The human environment includes human uses, social, cultural and economic values, and heritage resources.

These topics will be addressed in other submissions to the DOC-EERA by Enbridge.

1.4 OVERVIEW AND RATIONALE OF APPROACH TO ASSESSING THE LIKELIHOOD AND EFFECTS OF OIL RELEASES

1.4.1 Differences in Assessing the Effects of Routine Activities versus Accidental Releases of Oil

Environmental assessments are generally intended to predict the type and range of effects on the natural and human environment that could occur as a result of the construction, operation and decommissioning of a project. In addition, they typically describe recommended measures to mitigate and reduce effects of the Project, such as the effects of the routine activities during any phase of a project, as well as potential accidents and malfunctions.

However, there are number of key differences in how effects of routine activities differ from accidents and malfunctions (especially oil releases) and how they can be assessed. These include the following:

- While the effects of routine activities will or are likely to occur if the Project is constructed, operated and decommissioned, accidents and malfunctions and associated effects on the environment are, by definition, not common or may not occur at all. The likelihood of a large oil release occurring (i.e., the failure frequency) and the potential outflow volume (e.g., lower volume versus larger volume releases) are therefore important considerations in a risk assessment for an accident or malfunction.
- Effects of routine activities on the natural and human environment can be adverse (e.g., air emissions, loss of habitat) or positive (e.g., economic benefits). In contrast, effects of oil releases are almost always adverse. The significance of these effects to the natural or human environment will therefore depend on existing conditions and the characteristics of the resulting effects.
- While the specific effects of routine activities and infrastructure (e.g., the physical footprint, intakes and outputs to the environment) can often be predicted with a high degree of confidence through the multiple phases of the Project (e.g., construction, operation, decommissioning), the effects of an accidental release of crude oil must be based on a number of assumptions about the release and some form of modeling. Modeling results are specific to the assumptions and inputs used in modeling, including the conditions for the release (e.g., seasonal and weather conditions), the type and volume of crude oil released, the duration of the release, the specific location of the release, and several other factors. Modeling results for the same location can vary greatly, depending on the timing of the release (e.g., seasons, month), temporally-specific conditions such as weather and water flows (which can vary at scales of minutes to hours), release duration (instantaneous versus protracted duration of release), and other associated site conditions.
- Because there are differences in the certainty for routine activities (which will or will likely happen), versus a hypothetical release of crude oil (which may never happen), the resulting effects carry different weights or certainty. Routine activities are often quantified by estimating the physical and temporal overlap with environmentally sensitive components (e.g., distribution patterns of biota, movement patterns of biota, important habitats for fish or

wildlife, human use areas). There is less certainty in the estimates and likely spatial and temporal overlap of potential trajectories and site-specific behaviors of an accidental crude oil release with biological species or human uses. This is especially the case as species presence and human use also may be changing in space and time.
- When quantifying potential effects, the certainty of the value or benefit of mitigation measures for effects associated with routine activities is greater than those of accidents and malfunctions (i.e., a release of crude oil).

Statutes and regulations are in place that account for risks from potential future release incidents; this includes response preparedness and coordination, as well as full restoration of natural resource losses resulting from actual release incidents (i.e., the federal Oil Pollution Act and its implementing natural resource damage regulations at 15 United States Code of Federal Regulations [CFR] part 990).

1.4.2 Approach Used in Assessing Large Releases of Crude Oil

Given these differences in assessment approaches between routine activities and accidental releases, as well as the requirements for the assessment as described in the FSDD, the approach used for assessing the risks of a large release of crude oil from L3RP included several important components to improve an understanding of:

- How a large release of crude oil might occur and the likelihood of such a release (i.e., a threat assessment and failure frequency analysis)
- Likely trajectory and fate (i.e., behavior) of large unmitigated (i.e., no emergency response) releases of several types of crude oil under different environmental and seasonal conditions
- Range of potential effects an unmitigated large release of crude oil may have on the natural and human environment
- Potential and timing for the recovery of the natural and human environments following a large release of crude oil

To predict the potential threats, failure frequencies, and the trajectory and fate of hypothetical releases of crude oil, several representative sites along the preferred route for L3RP were suggested by the Consulting Team for consideration by the DOC-EERA and other state and federal agencies. Based on input from the DOC-EERA and these agencies, sites on some alternative routes were also considered. The approach for engagement of these agencies, the process used to select sites, and the methods used to characterize each hypothetical release location are described in Section 3.1.

The sites selected for the threat and failure frequency assessments, modeling of hypothetical releases, and assessment of effects were deliberately chosen to represent a variety of biophysical conditions, including the type and size of water features (e.g., size of watercourse, size of water body, speed and turbulence of water flow, and water depth), the type and density of vegetation cover, the type and intensity of land use, and human and ecological values. Issues raised through consultation with government agencies, affected stakeholders, the general public and native tribes also influenced the types of sites chosen. As discussed in Section 3.1,

LINE 3 REPLACEMENT PROJECT:
ASSESSMENT OF ACCIDENTAL RELEASES: TECHNICAL REPORT

Introduction
January 13, 2017

DOC-EERA coordinated a collaborative process with state and federal agencies to develop criteria for selection of preferred sites for modeling of hypothetical releases of crude oil and the assessment of effects. The criteria that were developed by this group took into account a range of biophysical conditions, as well as issues raised through consultation and regulatory processes.

For the assessment of large releases of crude oil from L3RP, once the criteria for selection of modeling locations had been determined, the needs of the assessment (as described in DOC-EERA 2015) were considered in developing the general assumptions for the spill modeling with respect to:

- **Type of crude oil:** To account for the differences in the types of crude oil that could be transported by the proposed L3RP, and the behavior of these crude oils within the environment, both a light crude oil (i.e., Bakken Crude) and two mixtures of a single heavy crude oil (i.e., CLB and CLWB) were considered. Note that CLWB was only used in winter time scenarios with low river flow conditions in the receiving water body. CLB was used in the spring high river flow and summer average river flow scenarios, corresponding to the seasonal availabilities of these two products.
- **Volume of oil:** To model a large release of crude oil (DOC-EERA 2015), a full bore rupture (i.e., complete severing of the pipeline) of the pipeline at a modeling site was modeled. In addition, conservative assumptions were used to account for the time for full shutdown of the affected pipeline (i.e., taking into account elapsed time for alarm notification, stopping the pumps, and closure of the shut-off valves). The maximum volume of crude oil hypothetically released at each site included both the initial release volume prior to shutdown (i.e., actively pumping out), as well as hydraulic drain down of the pipeline (i.e., gravity drained oil within the pipeline between the valves), following shutdown at that site.
- **Duration of model run:** To provide a conservative estimate of the trajectory and fate of crude oil, it was assumed that the maximum volume of crude oil released would flow downstream for 24 hours without mitigation (i.e., the initiation of an emergency response and clean up). However, modeling results were captured at 6, 12, 18, and 24 hours to approximate the downstream/down current extent and weathering of crude oil over the 24-hour period. Of note, a response would be initiated in a shorter period; therefore, this is a conservative assumption for these hypothetical release scenarios.
- **Seasonal differences in river flow conditions:** To account for seasonal fluctuations in the characteristics of water features, especially watercourses; high river flow (spring), average river flow (summer), and low river flow (winter) conditions were modeled at each site.
- **Seasonal differences in weather:** To account for differences in the behavior of several types of crude oil under different weather conditions, the corresponding weather information (e.g., temperature, wind speed) for each river flow condition (i.e., season) were identified and used in modeling.

Pinhole leaks were identified as a concern by regulators and the public; pinhole leaks are addressed in a separate report (Stantec and Barr 2016).

Based on the selection criteria for modeling locations (Chapter 3.0), the DOC-EERA, in collaboration with other state and federal agencies and the Consulting Team, chose seven representative sites across western, central, and northern Minnesota for modeling of hypothetical releases of crude oil. The seven sites represent a broad geographic range

throughout areas of Minnesota that could be crossed by L3RP. In combination, the seven sites represent a diversity of water features including large rivers down to small streams and ditches, with a range of flows from slow to rapid, varying amounts of turbulence, differences in channel types (e.g., sinuous to straight), and several lakes. They also represent a wide range of vegetation types and land uses, including several different forest types, protected areas, cultivated land, rice lakes, recreational areas, and human settlements.

For each of the seven representative sites that were selected, a threat assessment, failure frequency assessment, modeling of the potential trajectory and fate of large crude oil releases, and an assessment of effects to the biophysical and human environment were completed. Combined with the three flow conditions/seasons and the two types of crude oil (CLB and CLWB are considered one type of crude oil), the modeling completed for the seven representative sites equates to a total of 42 release scenarios (7 sites x 3 flow conditions x 2 types of crude oil).

During the public scoping comment period, questions were raised about the total number of sites to be investigated in these analyses. Some comments/questions implied that more than seven representative sites should have been chosen, with the same analyses completed for each site as those described in this report. Because the seven sites were selected to reflect a broad range of geographic and environmental characteristics, together they provide an understanding of a broad range of potential effects, should there be a large release of crude oil. This is consistent with the FSDD that "data generated from modeling at representative sites will be used to make broad environmental comparisons among and across routes in areas with similar features". Therefore, while modeling a larger number of sites may address site-specific concerns raised by stakeholders, the public, and native tribes, the incremental information gained regarding the potential fate of released crude oil and the associated range of effects would be marginal. The range of potential effects on the biophysical and human environment at these additional sites would not be expected to differ greatly from those assessed for the seven modeled sites.

It is the opinion of the principal authors of this report (as described in the preface) that additional modeling would not add proportionately to a better understanding of hypothetical releases of crude oil, nor would it change the conclusions of the anticipated environmental effects should there be a large release of crude oil. The breadth of water features and biophysical conditions included within the combined footprint of the seven modeling locations and the associated oil release trajectories are large. When this is combined with the seasonal differences and variable behavior of several types of crude oil, a broad range of potential environmental effects has been considered relating to physical and biological attributes of the environment and the socio-economic aspects and cultural values of the human environment (Chapter 7.0). It is the opinion of the principal authors of this report that adding additional modeling locations would not greatly alter the breadth of environmental effects considered, nor would it affect the conclusions that are made in this report.

1.5 USE OF THE OIL RELEASE MODELING INFORMATION

As noted in the FSDD, "information from the modeling is to be used to make broad environmental comparisons along and across routes in areas with similar features" (DOC-EERA 2016). The modeling of oil release trajectories and fate for each of the seven representative sites was intended to assist the DOC-EERA in addressing the environmental consequences of accidental large releases of crude oil as part of their broader assessment of the preferred and alternate routes for L3RP.

The analysis of environmental effects of an accidental large release of crude oil presented in this report (Chapters 5 through 7) is known as a consequence assessment. The intent of the assessment was to investigate the range of potential outcomes (effects) to the natural and human environment if an accidental release of a large volume of crude oil was to occur at any point along the pipeline (including preferred and alternative routes). The assessment involved quantitative modeling at carefully selected sites to predict the likely trajectory and fate and behavior of released oil, as well as assessments of the probable range of environmental effects under a variety of conditions. Through a careful and deliberate selection of representative sites across northern and central Minnesota, a broad spectrum of terrain, land-cover types, watercourses, waterbodies, wetlands, associated freshwater and riparian habitat types, vegetation, environmentally-sensitive areas, and human land uses were considered in the modeling and effects assessment. Therefore, this assessment can be used to consider the range of consequences that may be possible should there be an accidental release of crude oil along the proposed route or the proposed alternative routes for L3RP. Several different summary tables are provided in Chapter 3.0 to assist in the application of information from modeled locations to other locations.

As discussed in detail in Chapters 3 and 5, the consequence assessment for accidental large releases of crude oil involved quantitative modeling and assessment of potential environmental effects for 42 scenarios to demonstrate the anticipated range of outcomes that might occur in different seasons following an accidental large release of crude oil in a number of representative site conditions in central and northern Minnesota. The assessment considered:

- the range of product types (i.e., light and heavy crude oils) that may be shipped on the proposed pipeline
- environmental variability (i.e., 3 time periods including seasonal differences in river flow rate, snow/ice coverage, temperature, wind speed, etc.)
- biogeographic variability (i.e., 7 sites carefully chosen to represent different biotic and environmental factors, including climate, geology, topography, soils, hydrology, and vegetation, as well as human land use)

Results pertaining to the potential trajectory (movement), fate (behavior and weathering), and potential environmental effects of an accidental full bore rupture and resulting release of crude oil are provided for each of the scenarios. Together, these scenarios can be used to bound the

range of potential consequences at potential accidental release points in areas with similar features.

While seven specific representative release locations were investigated in this study, the careful and deliberate selection of the 42 representative release scenarios allows this consequence assessment to be used to determine the range of potential effects that may be possible should there be an accidental release at other locations along the preferred or alternate routes for L3RP. An equivalency table has been provided (Table 3-4) to aid users of this report in applying the results of the consequence assessment to other locations. Should an interested party have concerns over a specific watercourse that was not modeled, this table can be used to find an equivalent representative release location. From there, the interested party can consider the range of seasons to bound and/or determine the range of potential consequences for their specific location. As an example, should an individual near Bemidji be concerned about the possible effects of a release into Lake Irving, they can refer to Table 3-4 to find an equivalent site. The Lake Irving location includes a small watercourse (<10 m) that travels a short distance and connects to a lake/pond with recreational use and sensitive ecosystems. Upon comparison, the Shell River representative release location would be a logical substitute. Similarly, if one were to consider another release location that entered a medium watercourse that traveled a longer distance before entering a lake/pond system, they could consider the Sandy River representative release location as an equivalent site.

The term "representative" release location is used, as each site serves as a proxy for other similar sites. Because oil behaves similarly in water bodies and locations with similar geographic and environmental conditions, there is not a need to model multiple watercourses that have similar features. The predicted trajectory, fate, and effects results would essentially be the same or similar. While results would be very similar, there would be small differences in the actual downstream distance traveled and the potential location-specific sensitive receptors or regions of interest, should a release occur at a site that was not modeled. Similarly, should a release occur during a transitional season that was not modeled, the end result may be slightly different given differences in water flows, vegetation condition, etc. However, as the consequence assessment did include a broad range of geographic and environmental variability that are representative of the areas of Minnesota that are crossed by the preferred and alternate routes for L3RP, it is expected that the likely outcomes for sites not modeled would be bounded by the results provided in this report.

1.6 ORGANIZATION OF THE REPORT

This report consists of individual chapters that have been prepared by one or more members of the consultant team, consisting of Stantec, RPS, and Dynamic Risk. Enbridge prepared Chapter 2.0. The lead authors for each chapter of the report are identified in the Preface.

In addition to this Introduction, the report includes the following chapters and topics.

LINE 3 REPLACEMENT PROJECT:
ASSESSMENT OF ACCIDENTAL RELEASES: TECHNICAL REPORT

Introduction
January 13, 2017

- Chapter 2: Project Description—provides a description of the proposed L3RP.
- Chapter 3: Framing the Site Selection and Modeling Analyses—documents the approach used to frame the modeling analyses for L3RP. This chapter includes a summary of regulatory and agency engagement in developing release modeling scenarios, the identification of important considerations in modeling (e.g., hydrodynamic, seasonal, environmental, geographic, and oil chemistry considerations for modeling of crude oil releases), selection of oil release modeling tools, the development of criteria for selecting modeling locations, and the rationale for selecting specific sites for modeling.
- Chapter 4: Pipeline Failure Probability Analysis—this chapter includes an analysis of the types of threats that could cause failure, as well as a failure frequency analysis for each of the seven specific segments of L3RP associated with the modeling sites. As part of this analysis, a review of releases, as documented in the Hazardous Liquids Incident database of the U.S. Department of Transportation's PHMSA was undertaken.
- Chapter 5: Modeling of Crude Oil Releases—provides a description of the modeling tools used to predict the trajectory and fate of several types of crude oil under different seasonal conditions, including a description of key assumptions and the input data used for modeling.
- Chapter 6: Trajectory and Fate Results for Modeling Locations—this chapter describes the oil release modeling outputs for hypothetical, unmitigated, full bore releases of several types of crude oil and varying environmental conditions at the seven representative modeling locations in western, central, and northern Minnesota.
- Chapter 7: Assessment of Environmental Effects of Crude Oil Releases—the assessment begins with a description of the observed and expected effects of crude oil on key ecological and human receptors, including how crude oil behaves (i.e., its fate) in atmospheric, freshwater and terrestrial environments, followed by an assessment of effects for each of the seven representative sites. The assessment for each site includes a description of the environmental setting, the potential overlap of the modeled oil releases on High Consequence Areas (HCAs) and Areas of Interest (AOIs), and a description of the effects of a large release of crude oil on the natural and human environment.
- Chapter 8: Review of Environmental Recovery Following Releases of Crude Oil—this chapter describes the current state of knowledge of how various components of the natural and human environment are known to recover following a release of crude oil. The review focuses on information most relevant to environmental conditions in Minnesota. It also addresses how emergency response, clean up, and remediation measures can promote or impair recovery.
- Chapter 9: Summary and Conclusions—this chapter provides general conclusions on the risks of large releases of crude, including types of threats, the likelihood of occurrences of these threats for specific segments of the pipeline, the range of potential effects, including the benefits of emergency response, site clean-up and remediation, and environmental recovery of the receiving environment.

2.0 PROJECT DESCRIPTION

2.1 OVERVIEW

2.1.1 Line 3 Replacement Project

The integrity concerns on the existing Line 3 necessitate constructing of the proposed L3RP. Construction will consist of a new pipeline and associated facilities to replace Enbridge's existing Line 3 pipeline, which transports crude oil from the Joliette Valve in Pembina County, North Dakota to Clearbrook, Minnesota; and then on to an existing terminal in Superior, Wisconsin. The proposed L3RP route is approximately 363 miles long, 337 of which are in Minnesota. L3RP includes in Minnesota a new pump station and improvements at the existing Clearbrook Terminal, the expansion of three existing pump stations west of Clearbrook, and the addition of four new pump stations east of Clearbrook.

2.2 PROPONENT

Enbridge is the project proponent of L3RP.

2.3 PIPELINE ROUTES

2.3.1 Line 3 Replacement Project

Approximately 337 miles of new 36 inch diameter, underground crude oil pipeline would be constructed along the proposed L3RP route between the North Dakota/Minnesota and the Minnesota/Wisconsin borders, crossing portions of Kittson, Marshall, Pennington, Red Lake, Polk, Clearwater, Hubbard, Wadena, Cass, Crow Wing, Aitkin, and Carlton Counties.

West of Clearbrook, the L3RP route would generally follow the existing Enbridge Mainline Corridor and would be installed approximately 25 ft from the existing Line 67 pipeline. East of Clearbrook, the L3RP would generally follow other existing third-party pipelines, electric transmission corridors, and transportation corridors.

2.4 PIPELINE FACILITIES AND INFRASTRUCTURE

2.4.1 Line 3 Replacement Project

2.4.1.1 Clearbrook Terminal Modification

As part of L3RP, Enbridge would modify equipment and construct a new pump station at the existing Clearbrook Terminal, located near MP 909.4 of the existing Enbridge Mainline Corridor in Clearwater County, Minnesota.

2.4.1.2 Pump Stations

As described in Table 2-1, Enbridge would install three new pump stations adjacent to existing pump stations west of Clearbrook. The four new pump station sites would be located east of Clearbrook. Mainline valves, metering, monitoring equipment, and associated electrical facilities would also be installed at all facilities. In addition, Enbridge would install new pipeline inspector gauge launcher and receiver traps at the Backus Pump Station.

Table 2-1 L3RP Minnesota Pump Stations

County	Facility	MP	Description
West of Clearbrook			
Kittson	Donaldson	814.5	Expansion of pump capacity to 7,000 HP at existing Donaldson Pump Station
Marshall	Viking	848.2	Expansion of pump capacity to 7,000 HP at existing Viking Pump Station
Red Lake	Plummer	877.0	Expansion of pump capacity to 7,000 HP at existing Plummer Pump Station
Clearbrook			
Clearwater	Clearbrook Terminal	909.4	Installation of terminal connectivity, a new 7,000 HP Clearbrook Pump Station, PIG receiver and launcher traps, and injection from existing tanks 61, 62, 63 and 64
East Of Clearbrook			
Hubbard	Two Inlets	956.6	New 7,000 HP Pump Station
Cass	Backus	1,007.1	New 7,000 HP Pump Station and receiver and launcher traps
Aitkin	Palisade	1,061.7	New 7,000 HP Pump Station
Carlton	Cromwell	1,106.4	New 7,000 HP Pump Station

2.4.1.3 Mainline Valves

A valve is a shutoff mechanism that would be used to isolate a segment of pipeline in the rare event of a leak. At each valve location, Enbridge proposes to install the following equipment: a slab gate valve that would be remotely controlled from the Enbridge Control Center and that could be operated manually as well; digital pressure and temperature monitoring devices that would provide real-time pressure and temperature information to the Control Center; and associated electrical and communications equipment required to control the valve and monitor instrumentation.

2.5 PIPELINE CONSTRUCTION

For when pipeline construction is referenced at later parts of the report, the typical pipeline construction sequence is as follows.

First, appropriate safety measures would be implemented, including notification through the One-Call system to ensure third-party utilities and adjacent pipelines are properly marked. Next, the workspace would be surveyed, staked, and prepared for clearing. The workspace would then be cleared and graded, as necessary, to provide construction access and safe movement of equipment and personnel during construction. Silt fence[2] and other erosion control measures would be installed, and sensitive areas would be marked for avoidance. Pipe, valves, and fittings would be transported to the workspace by truck and placed along the workspace by sideboom tractors (also known as pipelayers) or cranes. After individual pipe sections are strung along the workspace, they would be bent to conform to the contours of the trench and terrain. The pipe segments would be lined up, clamped, welded, the welds inspected and subsequently treated with a protective coating. Trenching may occur before or after the pipe has been welded. Trenching is typically conducted using a backhoe or trenching machine. Where appropriate, topsoil would be segregated according to applicable permit conditions. The prepared pipe would be lowered into the trench and, where applicable, tied into existing facilities. Precautions such as padding the trench with soil would be taken during backfilling to protect the pipe from rock damage. During backfilling, subsoil would be replaced first and then the topsoil would be replaced.

[2] Silt fence: A silt fence is a sediment control device used on construction sites to protect nearby wetlands and waterbodies from stormwater runoff. A typical fence consists of a piece of synthetic fabric (sometimes referred to as geotextile fabric) stretched between a series of stakes where runoff is expected to reach wetlands or waterbodies. The fabric filters remove sediment from the water before it reaches the wetland or waterbody.

Once the pipeline has been welded and inspected and the trench has been backfilled, the pipeline would be hydrostatically tested[3] to ensure its integrity prior to the line being filled with crude oil and placed into service. The construction workspace would then be cleaned up and restoration activities would commence. Restoration would include implementing temporary and permanent stabilization measures such as slope breakers[4], mulching, and seeding.

[3] Hydrostatic testing: Hydrostatic testing is a process of verifying the integrity of the pipeline before it is placed into service. Hydrostatic testing involves filling the pipeline with water to a designated pressure and holding it for a specified period of time.

[4] Slope breaker: A slope breaker is an erosion control device to reduce stormwater runoff velocity and divert it from the disturbed construction area to more stable ground. A typical slope breaker consists of a ridge or channel constructed diagonally across the ROW on a hill.

3.0 FRAMING THE SITE SELECTION AND MODELING ANALYSIS

3.1 INTRODUCTION

As noted in the Introduction, the approach used for assessing the risks of a large release of crude oil from L3RP involves:

- Analyses of how a large release might occur and the likelihood of such a release
- Prediction of the trajectory and fate (behavior) of a large unmitigated release under different seasonal conditions, environmental settings and with different types of oils
- Assessment of the environmental effects on and recovery by the natural and human environment from hypothetical oil releases

As each of these aspects are strongly determined by the biophysical conditions at the time and location of the release, it is necessary to choose specific locations for these hypothetical releases, and make assumptions regarding the environmental conditions at the time of the release.

The DOC-EERA worked collaboratively with cooperating state and federal agencies and the Consulting Team to frame the selection of sites for hypothetical releases and develop specific assumptions about a release for use in the modeling analyses. The site selection process developed and implemented by this group was also informed by concerns and issues raised by members of the public, local communities, and Native American tribes during the scoping process.

This chapter describes:

- Engagement of state and federal agencies in identifying important considerations for site selection, including feedback from local communities and Native American tribes, and developing criteria for selecting sites for detailed assessment
- Process for identifying an array of potential sites for modeling of large oil releases along preferred and alternate routes, and then selecting a smaller number of representative sites for detailed assessment
- Rationale for the selection of the models used

This chapter concludes with an overview regarding how the modeling results are used in other sections of the report for understanding the potential effects of an accidental release of crude oil on environmental and human resources. The use of information from the threat assessment, failure frequency analysis, and modeling in planning emergency and remediation efforts is also discussed.

3.2 ENGAGEMENT IN FRAMING THE ASSESSMENT APPROACH

The engagement process for framing the assessment for large releases of crude oil involved three sequential approaches:

- Discussions with DOC-EERA to develop an overarching approach for the risk assessment of large releases
- Engagement of other State of Minnesota and federal agencies in refining the approach for assessment of large releases, including the development of criteria for selecting sites, the screening of candidate sites and the selection of sites for detailed assessment; and the selection of modeling tools and conditions for each of the selected sites
- Incorporation of scoping comments received from the public, local communities and Native American tribes in the approach for assessment of large releases of crude oil

3.2.1 Initial Discussions with DOC-EERA and Enbridge

DOC-EERA began investigating oil release modeling methodologies in July 2015, following the Commission's decision directing DOC-EERA to analyze the risk of pipeline ruptures. DOC-EERA met with representatives from Enbridge to discuss the types of approaches that might be used to assess the effects of large releases of crude oil. Technical consultants from Stantec and RPS were asked to provide technical support for these meetings.

Initial discussions focused on approaches for understanding the probability of a large release of crude oil and analyzing the potential effects of a large release of crude oil (e.g., purpose of modeling, types of models that could be used, and approaches for assessing potential effects to and recovery by important components or indicators of the natural and human environment).

Additional information was gathered and discussed that addressed the types of modeling tools, including a presentation on two modeling packages developed by RPS: OILMAP Land and SIMAP[5]. An example of the use of OILMAP Land for the Enbridge Line 3 Pipeline application to the National Energy Board in Canada was reviewed.

3.2.2 Engagement of Additional State of Minnesota and Federal Agencies

From October 2015 to March 2016, DOC-EERA met multiple times with state and federal agencies to discuss the approaches being considered for assessment of hypothetical large release of crude oil from the L3RP with a focus on developing approaches for selecting sites and the detailed analyses and modeling that would be conducted. State participation in the

[5] OILMAP Land and SIMAP are two separate computational oil spill modeling tools that have been developed by RPS to predict the trajectory, fate, and potential acute effects of released hydrocarbons on land and into water. Both models have been used extensively in the United States and internationally to meet regulatory requirements and other recommendations and guidelines. Computational oil spill models such as OILMAP Land and SIMAP meet these requirements and are used frequently by industry, government, and academia. See also Section 4.2.1.

consultations included representatives from DOC-EERA, the Minnesota Department of Natural Resources (MN DNR), the Minnesota Pollution Control Agency (MN PCA), the Minnesota Department of Agriculture (MN DA), and the technical consultant for the State of Minnesota, Cardno ENTRIX. At the federal level, the United States Army Corps of Engineers (USACE) was involved.

DOC-EERA also arranged for Enbridge, Stantec, RPS, and Dynamic Risk to provide technical presentations and participate in discussions with the attending state and federal agency representatives. These meetings occurred over a series of conference calls, in-person meetings, and workshops.

Key topics discussed during the various presentations included:

- Assessing threats to the pipeline and estimating the site-specific likelihood of an incident (i.e., failure frequency)
- Reviewing and providing guidance on modeling approaches for assessment of large release of crude oils. This included framing the desired information to be provided by modeling, selecting appropriate modeling tools and representative sites, and estimating the trajectory and fate of released hydrocarbons in space and time.
- Assessing the range of effects that might occur to different components of the natural and human environment if a release of crude oil were to occur

The primary focus of the Q4 2015/Q1 2016 meetings was the development of methods for predicting the behavior, eventual fate, and environmental effects of several hypothetical large volume releases of crude oil from L3RP spanning the diversity of the geographic and environmental conditions through areas of Minnesota where the pipeline passes. Other topics discussed included the assessment of pinhole leaks.

This dialogue yielded a number of recommendations regarding:

- Framing the modeling exercise with respect to the types of information to be provided through modeling and the assessment of effects
- Modeling tools to be used for predicting the trajectory and fate of oil releases (OILMAP Land and SIMAP were the models chosen)
- Data required for modeling (e.g., watercourse flows and characteristics, biophysical conditions, land use, and availability of data from state and federal agencies)
- Criteria for selection of specific sites for modeling of accidental releases, identification of a large number of potential sites, and subsequently the identification of the specific representative sites for modeling large release of crude oils (note: the potential locations that were considered, as well as the locations that were selected as representative site involved locations on both the preferred and alternative routes for L3RP)
- Variables to be modeled such as the type of release (full bore rupture), volume of the release at each site, the type of oil released, weather and seasonal conditions, receiving environmental characteristics, and flood stages
- Required documentation of modeling methods and results
- Assessment of environmental effects

In addition to the discussions on scoping, there also were separate meetings on pinhole leaks (addressed in Stantec and Barr 2016), the assessment of threats to the pipeline, and associated failure frequency analyses.

The results of consultation are further discussed in the sections below.

3.3 SELECTION OF MODELING RELEASE SITES

3.3.1 Environmental and Geographic Diversity along Pipeline Route

The preferred and alternative routes for the proposed L3RP pipeline traverse the width of Minnesota, starting in the northwestern part of MN (at the state border between Drayton, North Dakota and Hallock, Minnesota), and extending over 300 miles south-east before reaching the Wisconsin border south of Duluth (Figure 3-1).

The proposed pipeline covers a diversity of landscape and habitat types, including grasslands, agricultural lands, forests, streams, rivers, lakes, and wetlands. There are also regional and seasonal differences in aspects such as temperature, wind speed, river flow conditions, and amounts of rain, snow, and ice. Differences in terrain, land-cover types, habitat types, and land use exist and will influence how released crude oil might be transported over land into water features, as well as how much oil may be retained on different land and shore types.

3.3.2 Framing the Assessment of Hypothetical Large Releases of Crude Oil

During the initial meetings with the DOC-EERA and the state and federal agencies, discussions focused on the overall approach to the assessment of the fate and effects of large release of crude oils, important considerations with respect to natural and human environments, and the types of information that would be provided by oil release modeling.

Conservative choices for modeling purposes perform several functions. First, conservative choices tend to maximize predicted effects and help to improve our understanding of worst case outcomes with respect to oil trajectories, behavior and associated effects. Second, as not all factors can be anticipated, a conservative choice allows the model to bound upper and lower limits, thereby reducing the number of scenarios required, while still maintaining the integrity and likelihood of the model and scenario. Lastly, the modeling of worst case scenarios aids pipeline engineers and emergency response planners to better understand and prepare for a potential worst case scenario.

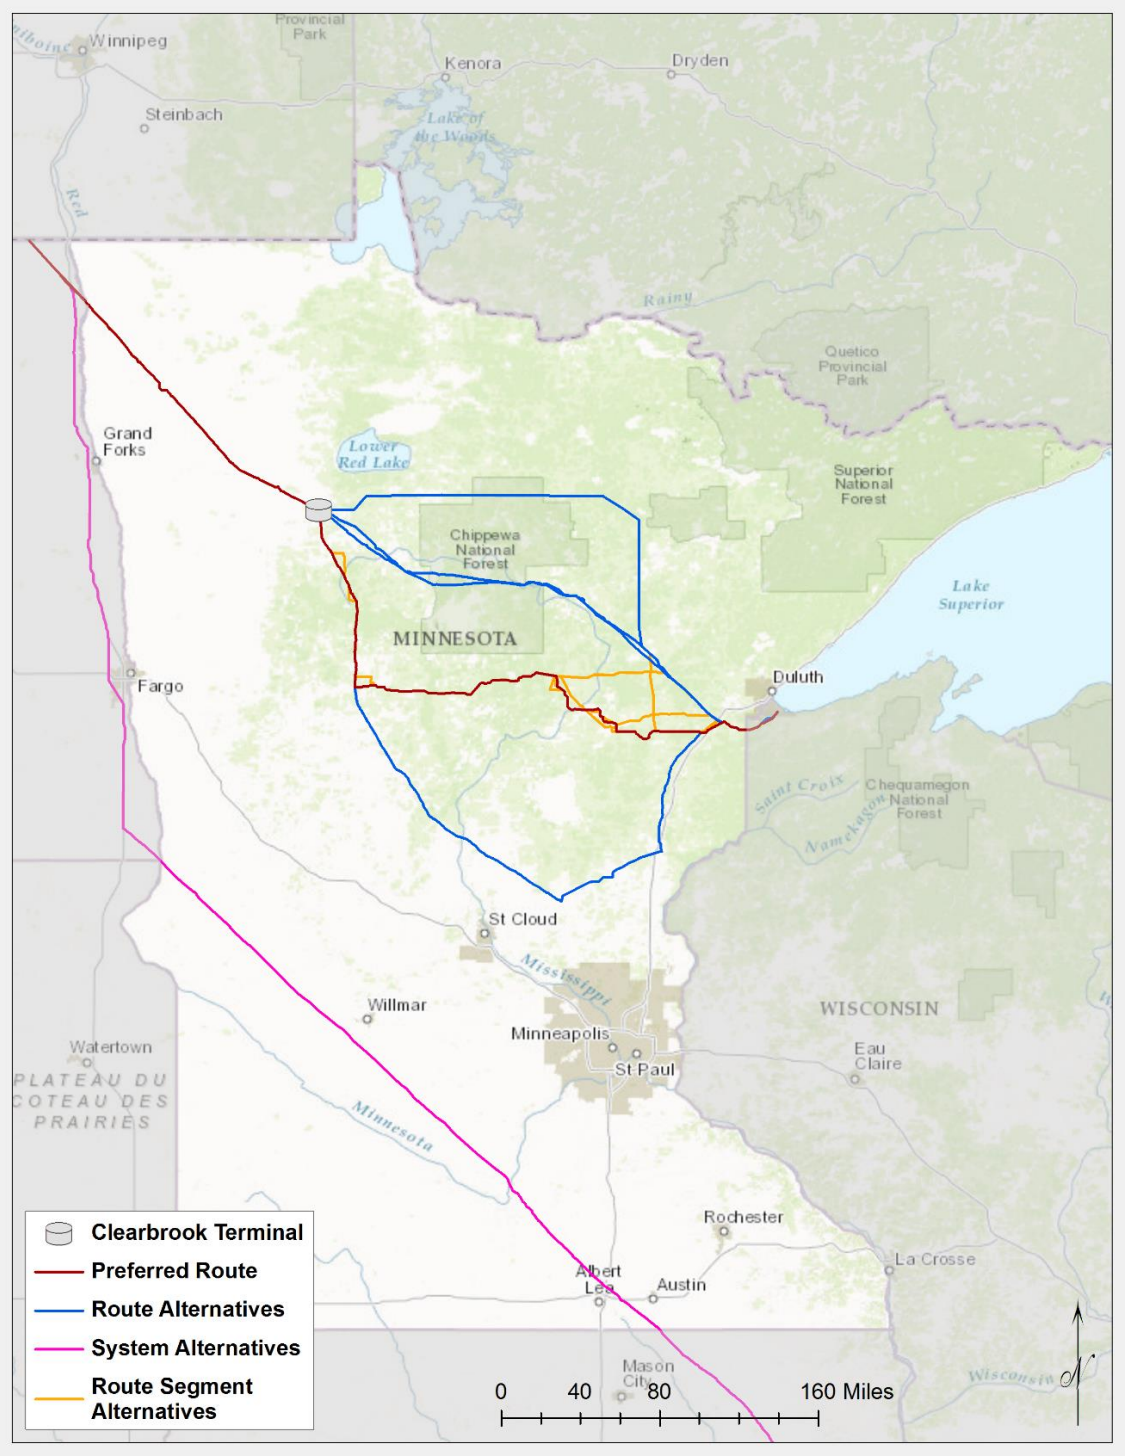

Figure 3-1 Map of the Preferred and Alternate Routes for L3RP

A primary consideration for developing appropriate scenarios for modeling of large releases of crude oil was the understanding that in the event of a full bore rupture incident (where the pipeline is essentially severed across the full diameter of the pipe), crude oil releases to land (as opposed to releases in water) often result in only small areas of land (i.e., a few acres) becoming contaminated by released oil. On land, crude oil will pool and collect in depressions and adhere to vegetation and soil. In contrast, if crude oil was accidentally released into water, crude oil can travel over larger distances due to water movement and the behavior of crude oil in water, thereby potentially exposing a larger area to contact with crude oil. This is not to suggest that effects of a release of crude oil on land would not be consequential, but it does justify the selection of locations for the hypothetical releases of crude oil that would result in oil entering watercourses (rivers or lakes) as being a conservative choice with respect to the fate, transport, and potential effects of released oil.

Given the larger spatial distribution possible from releases of crude oil into water features, unmitigated releases of oil would have greater potential to cause adverse effects to larger numbers and a greater diversity of ecological and human receptors downstream of the hypothetical release location. Therefore, it was decided that the modeling scenarios would focus on release locations where the hypothetical release of oil would either occur directly into a watercourse or would travel overland before reaching a watercourse. This approach was considered to be conservative with respect to the potential trajectory of released oil, the fate of released oil, and the potential effects of accidental oil releases on the natural and human environment.

Early discussions also focused on the type of releases to be considered and the specifics regarding these releases. Given that DOC-EERA wanted to focus on an assessment of potential large releases of crude oil (DOC-EERA 2015), the Consulting Team recommended that a full bore rupture (complete severing of the pipeline) be considered as a worst case scenario. A full bore rupture would result in a large instantaneous release of oil both through the initial release volume prior to shutdown (i.e., active pumping of oil), as well as the hydraulic drain down of the pipeline (i.e., gravity drained oil within the pipeline between the valves). This type of incident would result in more crude oil being released into the environment in a shorter period than partial ruptures or pinhole leaks (see Stantec and Barr 2016 for an assessment of pinhole leaks). While a full bore rupture is unlikely, it is again, a conservative choice used for modeling purposes. Accordingly, the maximum volume that could be released from each of the seven representative sites along the L3RP was calculated (Section 3.4); the specific maximum volume for that location was then used in the modeling of large releases of oil.

As a range of crude oils will be carried by the proposed pipeline, it was decided that several types of crude oil should be considered in the modeling of crude oil releases and the assessment of environmental effects. To reflect differences in the chemical make-up, density and viscosity of the crude oils that could be transported in the L3RP, a light crude oil (Bakken) and two blends of a heavy crude oil (CLB for spring and summer conditions, CLWB for winter conditions) were selected as representative crude oils that bound the anticipated range of products to be

shipped in the pipeline. The latter heavy crude oil would be representative of what is commonly referred to as diluted bitumen (i.e., dilbit). These two different types of crude oil were used in modeling and the assessment of environmental effects.

A number of issues and concerns were identified during public input to the regulatory review (e.g., via written submissions, comments during public meetings, and open houses) and through comments from the State of Minnesota and federal agencies. These issues and concerns were used to identify the type and range of conditions that would need to be considered in the assessment of large releases of crude oils. This information was also used to identify potential locations for the modeling of releases, as well as the types of issues and concerns that should be considered in the framing of the assessment of large releases of crude oil. Such modeling considerations included:

- Sites where the downstream movement of a crude oil release could overlap with and potentially affect a range of human uses (e.g., sources of drinking water, wild rice cultivation, agricultural lands, fishing, recreational uses, urban areas), as well as sensitive ecosystems (wetlands, sensitive fish spawning habitat for species such as walleye and trout, sensitive vegetation communities, forested regions, rare and endangered species).
- The need to assess potential effects of crude oil releases into large watercourses such as the Mississippi River. This reflected concerns for effects on environmental and human receptors, as well as concerns for interaction of the crude oil with suspended sediments in the water column and the potential for the oil-mineral aggregates, which may result in "sinking oil".
- The importance of considering differences in the characteristic of water features, including river width, the length of watercourses before entering larger water bodies, and differences in turbulence (e.g., flat calm water, riffles, rapids, and waterfalls) and other water feature characteristics (e.g., sediment loads, presence of emergent vegetation).

3.3.3 Development of Site Selection Criteria for Hypothetical Oil Releases

Information from the discussions with the public and state and federal agencies was used by the DOC-EERA and the Consulting Team in the development of specific criteria to guide the identification of the range of potential locations and the selection of a representative sites for modeling and assessment of hypothetical releases of crude oil.

The selection criteria for the modeling locations addressed engineering and environmental/ socio-economic considerations as follows:

- Be located so that a hypothetical large release of crude oil could potentially enter a watercourse; this included selection of locations where the hypothetical release of crude oil would either occur directly into a watercourse or would travel overland into a watercourse
- Be located where shut-off valves would not overly restrict the volume of crude oil that could potentially be released (i.e., the hydraulic drain down of pipeline would be a substantial contributor to the oil release volume)
- Include sites along both the preferred and alternate routes for L3RP

- Be representative of the geographic and environmental conditions and land uses along the proposed ROW for L3RP to aid in the evaluation of the range of potential effects to the natural and human environment along the pipeline
- Include a range of watercourse types (e.g., size, flow, energy level) and water bodies, including wetlands
- Support evaluation of potential effects to environmentally sensitive resources (e.g., spawning grounds for fish, wild rice lakes, or other sensitive habitats)
- Represent areas of expressed concern by Native American tribes, the general public, and/or state and federal agencies
- Support evaluation of potential effects to traditional use, other human use or infrastructure (e.g., potable water intakes or treatment facilities)

3.3.4 Identification of Potential Sites

A series of meetings was used to identify a number of candidate locations where modeling of crude oil releases might be conducted and, based on these candidate locations, select a suite of representative locations for the detailed analysis and modeling. The meetings involved representatives of the state and federal agencies, and the technical support consultant for the DOC-EERA, as well as Enbridge and their corresponding technical support consultants (Stantec, RPS, and Dynamic Risk).

Each water crossing transected by the preferred and alternative routes was identified and investigated as a potential location for hypothetical release modeling (major water crossings are shown in Figure 3-1). In total, nearly 1,000 watercourses were considered. The preferred route for L3RP transects 274 watercourses, and the alternative routes transect 641 watercourses.

To facilitate timely and effective modeling to inform decision-making, site selection criteria (described above) were then used to identify a number of candidate sites from the large number of watercourse crossings. Regions of interest to regulatory agencies and identified locations from discussions with the public were considered in selecting the candidate sites. Through several meetings with DOC-EERA, state and federal agencies, and the Consulting Team, a total of 27 candidate sites were identified for detailed evaluation as modeling locations. The selection of the candidate sites took into account the geospatial distribution of the sites along the preferred and alternate routes in central and northern Minnesota (Figure 3-2).

To facilitate the selection of the representative sites from the candidate sites, tables were constructed to summarize the attributes of candidate site with respect to:

- Location (within the portion of Minnesota crossed by the preferred and alternate routes for L3RP)
- Geomorphology
- Ecological land classification (see below)
- Location of sensitive resources or habitats in proximity to the preferred and alternate routes
- Watercourse characteristics
- Potential human uses (Table 3-1)

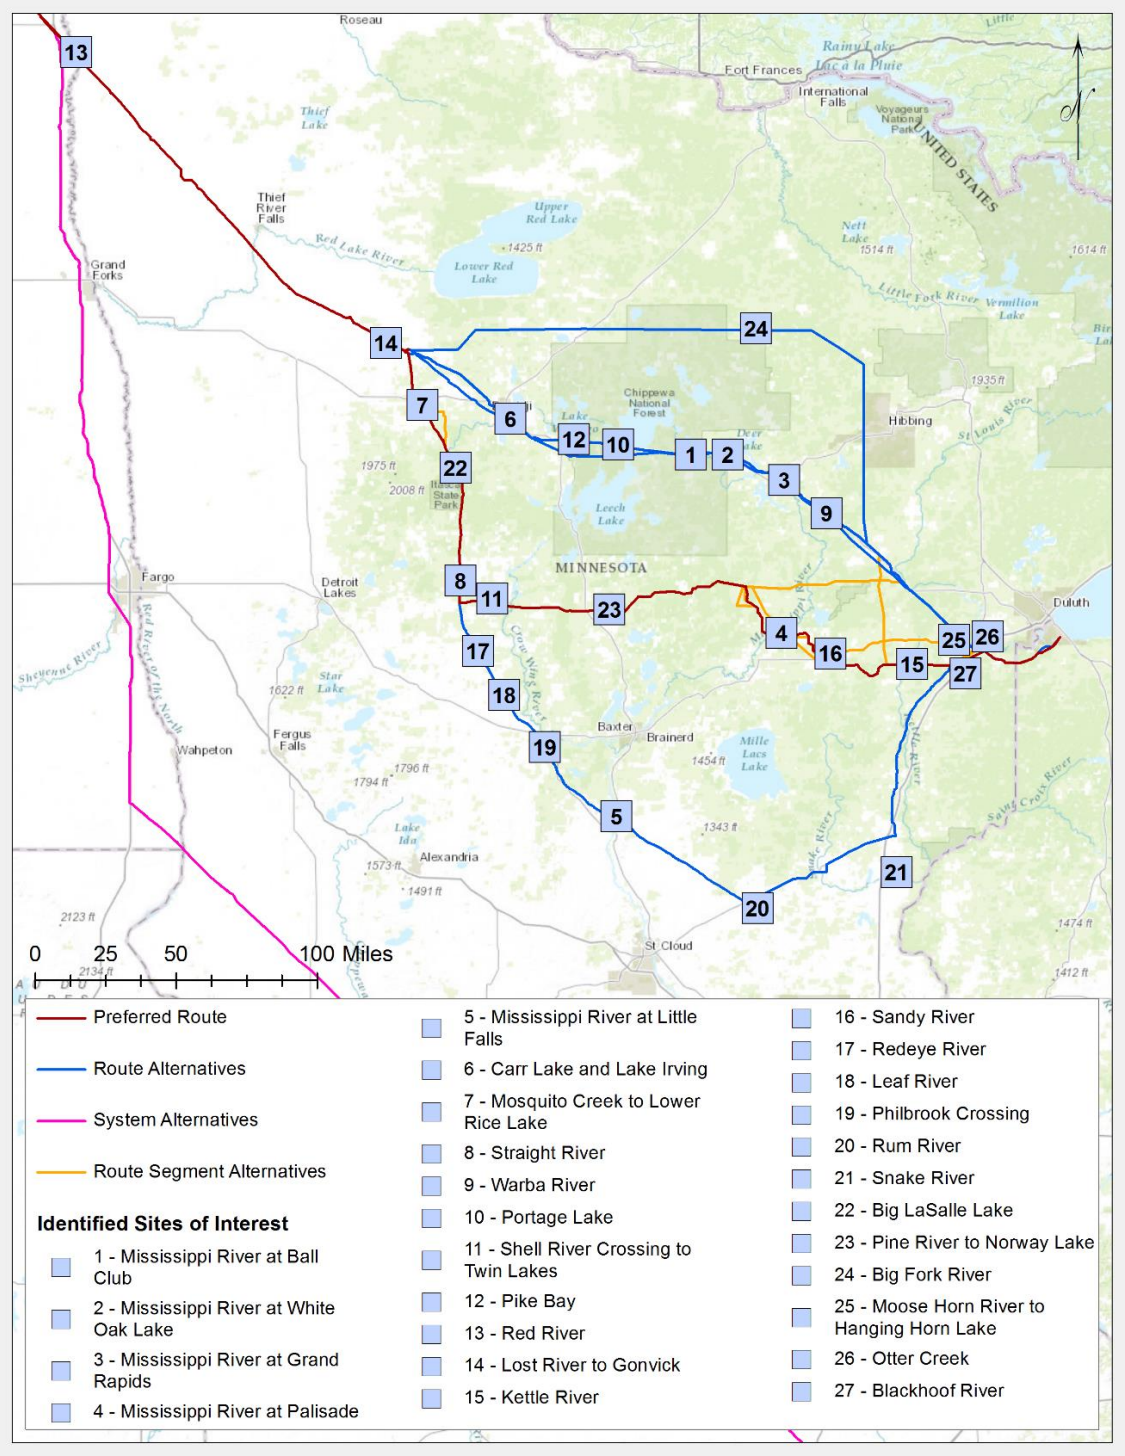

Figure 3-2 Candidate Locations Considered for Modeling along the Preferred and Alternative Routes for L3RP

Table 3-1 Characteristics of Candidate Locations for Modeling along the Preferred and Alternative Routes for L3RP

Site Name	Proposed Route	N	W	Nearest Municipality	Description	Rice Lake	Agricultural Land	Forested Region	Urban Area	Mississippi River	MN EcoRegion			River Width			River Length to Nearest Waterbody		Watercourse Characteristics			Identified Uses			
											Province	Section	Subsection	Small (<10 m)	Med. (10-50 m)	Large (>50 m)	Short (<5 km)	Long (>5 km)	Flat Water	Rapids / Falls	Lake	Recreational	Drinking Water	Populated Area	Sensitive Ecosystem
Big Fork River	Northern Alternative	47.760 810	93.625 157	Big Fork	Water crossing of Big Fork River (~25 m wide). River has many bends and does include sections with rapids passing through dense forest and some State Forest and Parks.			X			Laurentian Mixed Forest Province	N. Minnesota Forest & Ontario Peatlands	Littlefork-Vermillion Uplands		X			X		X		X	~		~
Blackhoof River	Preferred Route	46.603 105	92.553 646	Atkinson	Water crossing of the Blackhoof River (~5 m wide), with a sinuous marshy and scrub channel winding through forest and agricultural land before draining into the Nemadji River.		X	X			Laurentian Mixed Forest Province	Western Superior Uplands	Mille Lacs Uplands	X				X				X	~		X
Carr Lake and Lake Irving	Northern Alternative	47.447 557	94.886 677	Bemidji	Water crossing of (~25 m wide) river connecting Lake Irving and Carr Lake. The waterway is mainly lined by wetland passing beneath Route 2. To the south, Carr Lake contains wild rice, is lined with marshy wetlands and sporadic forest with some houses, and connects to Lake Marquette. To the north, Lake Irving has wild rice, two large marsh areas, residential housing along the banks, and an industrial complex of Bemidji on the north shore, connecting to Lake Bemidji. Shading legend:
Selected for a SIMAP Scenario
Selected for a OILMAP Land Scenario

The objective was to identify a smaller number of representative sites that would reflect most of the major attributes described above.

Minnesota uses an Ecological Classification System (ECS) for ecological mapping and landscape classification (MN DNR 1999). As stated by the MN DNR and the U.S. Forest Service: "Ecological land classifications are used to identify, describe, and map progressively smaller areas of land with increasingly uniform ecological features. The system uses associations of biotic and environmental factors, including climate, geology, topography, soils, hydrology, and vegetation. ECS mapping enables resource managers to consider ecological patterns for areas as large as North America or as small as a single timber stand and identify areas with similar management opportunities or constraints relative to that scale. There are eight levels of ECS units in the United States. Map units for six of these levels occur in Minnesota: Provinces, Sections, Subsections, Land Type Associations, Land Types, and Land Type Phases."

The ECS breaks the state up into 4 ecological Provinces (Figure 3-3), which include a total of 10 ecological Sections (Figure 3-4). Provinces are units of land defined using major climate zones, native vegetation, and biomes such as prairies, deciduous forests, or boreal forests. Sections are units within Provinces that are defined by origin of glacial deposits, regional elevation, distribution of plants, and regional climate.

Portions of the preferred and alternative routes for L3RP pass through each of the four Provinces (Table 3-2). The preferred route includes six Sections, while the alternative routes include eight Sections. Table 3-2 summarizes the locations identified in Table 3-1 by their respective Provinces and Sections.

3.3.5 Selected Sites for Modeling and Comparison of Site Characteristics and Equivalency

The DOC-EERA, together with state and federal agencies and the Consulting Team, employed the above criteria and considerations to select a total of 7 representative locations for detailed modeling and assessment from the 27 candidate locations; specifically:

- Site 1—Mosquito Creek to Lower Rice Lake
- Site 2—Mississippi River at Ball Club
- Site 3—Sandy River
- Site 4—Shell River to Twin Lakes
- Site 5—Red River
- Site 6—Mississippi River at Palisade
- Site 7—Mississippi River at Little Falls

For each of the seven modeling locations, the following detailed analyses were completed.

- An assessment to identify the potential threats to the pipeline from natural and human causes at the modeling location, and an assessment to quantify the failure frequency for a full bore rupture specific to the conditions at that location (i.e., within the potential impact segment; Chapter 4.0). The maximum volume of crude oil that could be hypothetically released at each site was determined based on the pipeline specifications and topographic conditions in proximity to each modeling location. The maximum volume out was calculated as a full bore rupture, with a conservative response in the pipeline Control Center of a maximum of 10 minutes, followed by a 3-minute period to allow for valve closure, and then drain-down of the elevated segments of pipeline. The maximum 13-minute duration of Control Center response time to valve closure is a standard for safe operations and leak detection for Enbridge. The total volume out included both the initial release volume prior to shutdown (i.e., actively pumping out), as well as hydraulic drain down of the pipeline (i.e., gravity drained oil within the pipeline between the valves), following shutdown at that site.
- The trajectory of an unmitigated oil release and the associated fate or behavior of the crude oil (i.e., weathering and physical distribution [e.g., on shore, on the water surface]) was predicted for each location using two different modeling tools (see Chapters 5.0 and 6.0). The volumes used in the hypothetical release were based on the largest quantity of oil from the L3RP pipeline at that specific location. At each location, separate models were run for three flow conditions for watercourses (low, average and high) and three types of crude oil (Bakken crude oil, CLB, and CLWB). Maps of the trajectory of the release and tabular summaries of the fate of the crude oil were developed for 6, 12, 18, and 24 hours following the hypothetical release.
- The effects of the hypothetical release of crude oil at each location on key receptors in the natural and human environment were assessed using two methods. The first method involved determining the potential overlap of the predicted trajectory of an oil release on HCAs, as defined under federal law, and AOIs, as defined under state law (Chapter 7.0). The HCAs were based on the PMHSA data for each location. The types of AOIs to be considered were identified by the state and federal agencies and included databases from the MN DNR. The second method considered known effects of crude oil releases on key receptors, with a focus on ecological and human health risks. The recovery of the natural and human

environment from exposure to crude oil, based on current literature, is discussed in Chapter 8.0.

As shown in Figure 3-5 and summarized in Table 3-3, the seven representative modeling locations are well distributed along the preferred and alternate routes for L3RP. To better illustrate how the seven representative modeling locations represent different combinations of hydrological conditions, watercourse widths, water features and uses, the detailed summary of features and characteristics (i.e., site attributes) described in Table 3-1 was condensed into a simpler format (Table 3-3). As shown in this table, for each attribute and the specific categories within each attribute (other than overland flow), at least two of the representative modeling locations and typically several were representative of that specific attribute and category. This summary demonstrates that the seven representative modeling locations did include a robust diversity of site characteristics that were identified in the scoping sessions. This included the features that are representative of most of the predominant ecological units along the pipeline, as well as the major hydrological features, watercourse widths, watercourse features along the preferred and alternative routes.

It is the opinion of the authors of this report that the modeled crude oil releases under different seasonal flow conditions and the predicted trajectory and fates information at each of the seven modeled sites will adequately represent the likely outcomes of an oil release in central and northern Minnesota. In combination with a broader understanding of the literature regarding the effects of an oil release on key receptors in the natural and human environment (Section 7.1), as well of site-specific assessments of potential effects on environmentally-sensitive areas (e.g., HCAs and AOIs; Section 7.3) and on key receptors at each of the seven modeling locations (Sections 7.4 to 7.10), a wide range of potential effects on key receptors under different seasonal flows conditions and with light and heavy crude oils are considered and analyzed. Further, the authors of this report believe that modeling and assessment of effects at additional inland sites would not add proportionately to a better understanding of environmental effects stemming from hypothetical oil releases, nor would additional modeling change the conclusions of the anticipated environmental effects, should there be a release of oil.

3.3.6 Description of Representative Release Locations

3.3.6.1 Site 1—Mosquito Creek to Lower Rice Lake

The Mosquito Creek to Lower Rice Lake modeling location captures both the potential for overland flow of crude oil and the downstream transport of crude oil in a very small watercourse. The hypothetical release location is in a relatively flat, forested region that forms a drainage area that has a gentle slope towards agricultural and grassland habitats. The swale collects into a narrow and seasonal water crossing that ultimately forms Mosquito Creek, a channel approximately 3 ft in width that flows to the south and west. Mosquito Creek flows through marshy grassland and sporadic forest, cutting through agriculture and nature reserves. After approximately 12.5 miles, the watercourse grows to around 35 ft in width, before entering Lower Rice Lake. Lower Rice Lake is approximately 1,600 acres in size and supports large areas of wild rice.

This modeling location represents the environmental conditions of a small quiescent watercourse that contains wetlands, marsh, and fen. The agricultural lands, nature preserve, and wild rice that may be present are representative of lands that may be used as a source of food and recreation. In addition, portions of the ecosystem have been classified as sensitive (i.e., included in the PHMSA database for HCAs and/or the State of Minnesota data base for AOIs).

3.3.6.2 Site 2—Mississippi River at Ball Club

The Mississippi River at Ball Club modeling location contains a sinuous water channel that is approximately 80 ft wide. The channel flows to the south and east through a relatively well defined channel that has a large number of oxbows. The banks are lined with extensive wetlands and forested areas adjacent to some parts of the water course. Under high river flows, the watercourse connects to White Oak Lake, before extending to the south through more sinuous channels and marshy wetlands.

This modeling location captures the environmental conditions of a quiescent watercourse of intermediate size that contains wetlands, marsh, and fen. The lake is approximately 9 miles downstream of the hypothetical release location. This location is representative of lands where food may be harvested, including fish and wild rice. In addition, the location includes an upstream portion of the Mississippi River and forested land. This region is used for outdoor recreation, and near the populated area of Deer River and sensitive ecosystems.

3.3.6.3 Site 3—Sandy River

The Sandy River modeling location is a bifurcated channel, approximately 30 ft wide, and flows to the west. The southern channel is a natural sinuous feature, while the northern channel is a straight drainage-type ditch. The waterway is mainly lined by marshy grasses and wetland with some forests. The river flows through Steamboat and Davis lakes to Flowage Lake and eventually Big Sandy Lake. The region is known to contain fish spawning habitat.

This modeling location captures a small ditch/creek type water course that enters into lakes and ponds after passing through areas with wetlands, marsh, and fen. The lakes are between approximately 6 and 12 miles downstream. The site is representative of forested and agricultural lands where food may be harvested. Due to the fish species present, this watercourse is used for recreation, specifically focused around recreational fishing. The region is known to contain sensitive ecosystems.

3.3.6.4 Site 4—Shell River to Twin Lakes

The Shell River Crossing to Twin Lakes modeling location contains a straight marshy channel, approximately 80 feet wide, that passes through forested areas that are nestled between agricultural lands. The watercourse enters the northern end of Upper Twin Lake before draining into a small reach that feeds Lower Twin Lake. There are many houses lining the lakes, with docks that provide access to swimming and boating.

This modeling location captures a medium width quiescent watercourse that enters directly into lakes after passing through areas with wetlands, marsh, and fen. The lakes are approximately 0.6 to 1.2 miles downstream of the hypothetical release location. The presence of residences with docks does make this location representative of inhabited areas that may be used recreationally. In addition, this region is known to contain sensitive ecosystems.

3.3.6.5 Site 5—Red River

The Red River is located along the border of Minnesota and North Dakota, and runs to the north into Canada. The pipeline crossing is located approximately 3 miles (4.82 km) due east of Bowesmont, North Dakota and 9 miles (14.48 km) southwest of Hallock, Minnesota adjacent to Route 16. At the proposed pipeline crossing location and downstream, the Red River is a large, wide (150–400 ft) river that flows north along a well-defined sinuous channel. The Red River passes the communities of Pembina, North Dakota and St. Vincent, Minnesota approximately 32 river miles downstream from the crossing location, and crosses into Canada approximately 34.5 miles downstream. The communities of Emerson and West Lyme, Manitoba are located on the Canadian side of the international border.

This modeling site captures a large, low-gradient (dropping approximately 6 ft in 35 river miles) watercourse, with a sinuous channel that is subject to flooding. The shore types are predominantly vegetated, often with shrubs and trees above the level of ice-scour. These waters are known to be a major area for recreation use, and also pass through or adjacent to sensitive ecosystems. The riparian banks are generally well vegetated, including some trees. Patches of forest are often present where the river meanders, although the surrounding land use is primarily agricultural. The Red River is subject to moderate to extreme flooding, particularly in the spring. Under low or average flow conditions, the stream banks are a combination of grass and soil. Under higher flow conditions the river can overtop the banks and spread into the surrounding farm and grassland.

3.3.6.6 Site 6—Mississippi River at Palisade

The Mississippi River at Palisade modeling location is a large river, approximately 250 ft wide, which flows to the south and west. The hypothetical release location is approximately 1 mile south of Palisade, MN. The sinuous channel is mostly flat water passing through a number of oxbows. There are some turbulent waters with the presence of a flood diversion dam and spillway. Under high flow rates, this small region would have very turbulent waters containing rapids from a waterfall. The banks are mainly forested, with residences and some agricultural lands on either side.

This modeling location captures the environmental conditions of a large and relatively quiescent watercourse that has predominantly forested banks. In addition, the site does include a midstream portion of the Mississippi River and forested lands. While the majority of the channel is relatively flat water, the flood diversion channel, with its dam and spillway, have the potential to result in localized turbulence, that could entrain oil if a release were to occur and crude oil was to reach the spillway. The sinuous channel is used recreationally and contains sensitive ecosystems. In addition, the watercourse is known to be a source of drinking water to residences in the area.

3.3.6.7 Site 7—Mississippi River at Little Falls

The Mississippi River at Little Falls modeling location is a large river, approximately 820 ft wide, which flows to the south. This modeling location captures the environmental conditions of a large watercourse that has predominantly forested banks. The hypothetical release location is approximately 5 miles north of Little Falls. This small urban area contains the Little Falls Dam, which has a large waterfall that induces a large amount of turbulence, which would entrain surface oil into the water column, if a release of crude oil were to travel downstream to this dam. A second dam and waterfall, known as the Blanchard Dam, is located approximately 8 miles downstream of Little Falls, providing the potential for further entrainment of crude oil into the water column in the event of a release. The shore types in this region are mainly forested, with some small portions of agricultural lands and urban areas along the banks. The waters are used recreationally and sensitive ecosystems are present.

3.4 SELECTION OF MODELING TOOLS

3.4.1 Approach

The types of models to be used to predict the trajectory and fate of hypothetical releases of crude oil were discussed at the initial meetings with the State of Minnesota and Enbridge. The types of models, including the desired output information, were also discussed during the initials meetings with state and federal agencies and Enbridge. Through these discussions, it was agreed that modeling of the trajectory and fate (i.e., behavior and weathering) of hypothetical releases would be conducted using both the OILMAP Land and SIMAP computation models.

OILMAP Land provides a two-dimensional prediction of the trajectory and fate of the released crude oil (i.e., downslope and downstream in the horizontal direction), whereas SIMAP provides a three dimensional prediction (i.e., movement in both the horizontal and vertical directions, meaning the possibility for movement within the water column and on bottom sediments). Because SIMAP calculates the trajectory and fate of crude oil in three dimensions, it is a considerably more complex model that contains more interactions and processes and requires more site-specific data than OILMAP Land. Both are state-of-the-art models used by industry, government, and academics throughout the world.

Both models have been used extensively in the United States and internationally to meet regulatory requirements and other recommendations and guidelines. The PHMSA regulations (CFR, Title 49, Parts 190-199) discuss hazardous liquid integrity management, stipulating identification of HCAs and determination of direct and indirect effects from a potential spill, which are addressed with this modeling. Regulatory requirements for pollution control in offshore waters are overseen by the Bureau of Safety and Environmental Enforcement, with 30 CFR 254 requiring worst case trajectory modeling. For inland waters, the U.S. Environmental Protection Agency (USEPA) oversees Spill Prevention, Control, and Counter-measure and Facility Response Plans. Finally, increasingly comprehensive regulations for transportation of crude by rail have begun with rulings from the U.S. Department of Transportation Federal Rail Administration. The SIMAP model also has been used on numerous Natural Resource Damage Assessments (NRDA).

As shown in Table 3-4, either the OILMAP Land or SIMAP model was used at each representative location. The choice of model for each location was based on the characteristics of the site, as well as the desired outputs from the modeling. SIMAP was chosen for two of the sites on the Mississippi River. This was primarily based on a desire by the State of Minnesota to better understand how turbulent flow could result in the entrainment of crude oil from the water surface into the water column, and the possibility for the creation of oil-mineral aggregates which have the potential to sink (i.e., "sinking oil"). The two modeling locations on the Mississippi River chosen for SIMAP include dams and waterfalls downstream of the hypothetical oil release location. OILMAP Land was used at the remaining five sites. More detailed descriptions of each of the models and their application is provided below.

Unmitigated releases (i.e., no emergency response to contain or remove released oil) were simulated at each hypothetical release location, using a range of site-specific environmental conditions over multiple seasons.

[NONPUBLIC DATA HAS BEEN EXCISED...

Table 3-4 Locations and Predicted Volume Out for the Representative Release Locations

Case #	Representative Release Location	Latitude (N)	Longitude (W)	Model Used	Predicted Volume Out (bbl)[1]
1	Mosquito Creek to Lower Rice Lake	47.4604	95.3066	OILMAP Land	
2	Mississippi River at Ball Club	47.2360	93.9596	OILMAP Land	
3	Sandy River	46.6263	93.2431	OILMAP Land	
4	Shell River to Twin Lakes	46.8196	95.0430	OILMAP Land	
5	Red River	48.70533	97.1148	OILMAP Land	
6	Mississippi River at Palisade	46.6983	93.4950	SIMAP	
7	Mississippi River at Little Falls	46.0483	94.3420	SIMAP	

NOTE:

[1] The maximum volume of oil hypothetically released at each modeling location included both the initial release volume prior to shutdown (i.e. actively pumping out), as well as hydraulic drain down of the pipeline (i.e. gravity drained oil within the pipeline between the valves), following shutdown at that site. The calculation is specific to the pipeline and topographic conditions at the modeling location.

...NONPUBLIC DATA HAS BEEN EXCISED]

As noted earlier, multiple modeling runs were completed for each of the seven release locations. A total of five release locations were modeled using OILMAP Land, while the remaining two were modeled using SIMAP (Table 3-4). This involved separate model runs for each of the two oil types (Bakken crude oil and CLB[6]) for each of the three flow conditions/seasons (high water flow—corresponding to spring; moderate water flow—corresponding to summer and fall; and low flow—corresponding to winter). In total, 42 physical fates scenarios were modeled (7 sites x 2 crude oils x 3 flow conditions/seasons).

Each of the hypothetical unmitigated releases was modeled for 24 hours, with outputs provided at 6, 12, 18 and 24 hours. The 24-hour duration for an unmitigated release was chosen as it is a conservative assumption that the release would be unmitigated for 24 hours, and that the released crude oil would travel downstream unimpeded for that length of time. A similar duration and time steps were used for the ecological and human health risk assessment for Line 3 in Canada that was submitted to the National Energy Board of Canada (Enbridge 2015).

[6] Two crude oil types were considered: Bakken crude oil and CLB. The composition of CLB varies throughout the year. Therefore, the properties of CLB during the summer and winter were determined. A Cold Lake Summer Blend (CLSB) was used for modeling of the average (summer) and high (spring) conditions, whereas CLWB was used for modeling of winter conditions.

3.4.2 OILMAP Land

OILMAP Land is a two-dimensional modeling system that is used to simulate the movement of released oil in the environment. It simulates the flow of oil or chemicals over land as it travels over the land surface and into any surface water body. The model itself has three components, including the overland release model, the surface water transport model, and the evaporative model that define the weathering of oil in the environment under specified conditions. The outputs include an assessment of overland and downstream trajectory of crude oil and resulting locations (e.g., shoreline reaches or segments) where oil may be found at specific times following a release. A simplified mass balance is provided to determine how much oil is retained on land, evaporates, is on the water surface, or oils shorelines. The trajectory results from OILMAP Land can be used in an HCA and AOI analysis, which consists of overlaying the presence of oil onto specific identified regions of interest to determine which resources potentially may be affected.

At each of the five modeling locations where OILMAP Land was used, the trajectory and fate of the hypothetical release of crude oil into riverine and lacustrine environments were modeled based upon the assumption of a full bore release and drain down (Table 3-4). Worst-case release volumes, based on a full bore release for 13 minutes and complete drain down, were calculated for each location. The methodology used to calculate release volumes may be found in Section 4.2. Three seasonal and environmental conditions were modeled, including high, average, and low river flows that represented spring, summer, and winter conditions, respectively. Two oil types were modeled for each flow/season at each site, including Bakken crude and CLB. The chemical and physical parameters of CLB were varied between warmer conditions (CLSB was used for spring, summer/fall conditions) and winter months (CLWB was used) due to changes in the composition of the oil over the course of a year.

For each of the three flow-defined seasons, scenarios for the hypothetical oil releases were run under the corresponding environmental conditions including temperature, wind speed, the concentration of total suspended solids within the water column, etc.

3.4.3 SIMAP

SIMAP is a three-dimensional modeling system that is used to simulate the physical fates of crude oil in the water. It estimates the distribution (as mass and concentrations) of whole oil and components of oil on the water surface, on shorelines, in the water column, in sediments, and evaporated to the atmosphere. This comprehensive modeling system allows for a more in depth understanding of the behavior of oil in the environment, when compared to OILMAP Land. Oil fate processes included in SIMAP are oil spreading (gravitational and by shearing), evaporation, transport, randomized dispersion, emulsification, natural entrainment, dissolution, volatilization of dissolved hydrocarbons from the surface water, adherence of oil droplets to suspended sediments, adsorption of soluble and sparingly-soluble aromatics to suspended sediments, sedimentation, and degradation.

The outputs of the SIMAP physical fates model include the distribution of the released crude oil in three dimensional space and time. This can include the cumulative area covered by a thickness of oil on the water surface, volumes of water at various concentrations of dissolved aromatics and total hydrocarbons, masses of total hydrocarbon and aromatics on surface sediments, and the lengths and location of shoreline affected by oil.

At each of the two modeling locations where SIMAP was used, the effects of potential releases into riverine environments were modeled at each location based on the assumption of a full bore release (Table 3-4). The same three seasonal and environmental conditions, two types of crude oil, and approach for determining the site-specific release volumes modeled in the OILMAP Land assessment were used for the two SIMAP sites.

4.0 PIPELINE FAILURE PROBABILITY ANALYSIS

As part of the route permitting process for L3RP, the MN DOC-EERA was directed to complete an environmental review. The review was required to include an assessment of the risk of large oil releases, including the probability of such events, modeling of oil releases, and an assessment of the potential corresponding environmental effects.

Risk is commonly defined as the product of the probability of an event occurring (i.e., an oil release) and the resulting consequence (i.e., trajectory, fate and effects) of a release. This chapter focuses on the first component of risk: the probability of a large oil release occurring.

To address the probability of a large oil release, quantitative estimates of rupture frequency were determined for each of the seven modeling locations. In linear infrastructure such as pipelines, the probability of failure over a given time period is proportional to segment length, with longer segments being associated with greater probabilities. Therefore, given that each of the seven sites were associated with river crossings, the length of the pipeline segment that was considered in the failure frequency analysis for each modeled site was established through a high resolution analysis of outflow and overland spill modeling of full-bore rupture release scenarios. Specifically, the failure frequency analysis for each site considered the longest length of pipeline around the river crossing where crude oil from a hypothetical full bore rupture was predicted to reach the immediately adjacent waterbody. This analysis took into account both direct releases into the waterbody, as well as local topography and land cover type on each side separately, as well as the associated overland flow.

Having established the segment length at each of the seven modeled sites, quantitative estimates of rupture frequency were made, based on a two-step analysis. The first step involved a Threat Assessment in which the relevant threats at each site were identified (described in Section 4.2). As part of the Threat Assessment, approaches for quantifying threat-specific rupture frequency were selected, giving consideration to threat attribute data, as well as best practice methodologies. Using these approaches, threat-specific quantitative estimates of rupture frequency were then generated in the second step of the analysis—the Frequency Analysis (described in Section 4.2).

4.1 THREAT ASSESSMENT

4.1.1 Overview of the Threat Assessment

The primary objective of the Threat Assessment was to evaluate the potential threats to the integrity of the L3RP at each of the seven modeling locations. The threat assessment approach described in ASME B31.8S (Attachment A) was used as the basis of the Threat Assessment. Threats were divided into nine categories, plus an additional category (Other Threats):

- External corrosion
- Internal corrosion
- Stress corrosion cracking (SCC)
- Manufacturing defects
- Construction defects
- Equipment failure
- Third party damage
- Incorrect operations
- Weather related and outside force
- Other threats (e.g., forest fires, concomitant failures, access restrictions, and exposure to vandalism)

As the results of the threat assessment form the basis of a subsequent analysis to provide quantitative estimates of the likelihood of failure at each of the seven sites, the other objective of the threat assessment is to establish candidate approaches for estimating failure likelihood based on the availability, quality, and completeness of the data attributes for each threat.

The results of the threat assessment showed that of all threats considered, only two (SCC and "Other" threats) are characterized as negligible (i.e., given the location, materials and design/build specifications of the L3RP, these threats do not contribute in a substantial way to the overall failure likelihood). Additionally, the threat of Equipment Failure was considered out of the scope of this assessment, since there are no non-pipe components within the study area for any of the seven modeling locations. For the remainder of threats, quantitative estimates of failure frequency were made in a separate failure frequency analysis.

4.1.2 Introduction

The primary objective of the threat assessment is to review the attributes for all potential threats to a pipeline system taking into account the design, materials, construction methods and operational variables for the pipeline system of interest. Through this review, the relevance and severity of each threat can be assessed in the context of the operating environment for the pipeline being reviewed.

As a variety of failure likelihood estimation approaches exist, with each requiring specific data sets, the threat assessment also considered the availability and type of data for each threat to

assist in the selection of the optimal approach of determining the failure frequency for that threat.

This Chapter is structured as follows:

- Section 4.1.3: Scope—description of the pipeline segments being addressed by the threat assessment documented in this report, as well as a description of the future operating conditions that are likely for the pipe segments for the seven modeling locations
- Section 4.1.4: Threat Assessment Approach—identification of the threats considered and a description of the approach
- Section 4.1.5: Assessment of Threats—review of all threat attributes and an assessment of threat potential
- Section 4.1.6: Threat Potential Summary—summary of the threat potential for each threat, as well as description of the candidate approaches for estimating failure likelihood based on the availability, quality, and completeness of the data attributes for each threat

4.1.3 Scope

The threat assessment was conducted for seven separate segments of the 36 inch outside diameter (OD) L3RP. At each of the seven modeling locations, the segment length for each pipeline was determined by outflow and overland spill analysis. Specifically, the threat assessment and failure frequency analysis for each site considered the length of pipeline around the site of the hypothetical full bore rupture from which a crude oil release could affect (i.e., reach) the immediately adjacent waterbody through direct release or overland flow.

The design details of these seven pipeline segments are summarized in Table 4-1. Aerial imagery of each of the seven modeling locations is provided in Figure 4-1 to Figure 4-7.

Table 4-1 L3RP Pipe Segment Summary

Site No.	Stationing			Mile Post			Design Details				Installation

4.1.4 Threat Assessment Approach

The threat assessment was based on ASME B31.8S (Attachment A). Although the scope of ASME B31.8S is the management of system integrity of gas pipelines, this standard was employed as the basis of the threat assessment due to the comprehensive list of threats considered in Attachment A, and the applicability of these threats to crude oil pipelines. Based on this standard, threats are divided into nine categories, plus an additional category (Other Threats).

- External corrosion
- Internal corrosion
- SCC
- Manufacturing defects
- Welding / fabrication defects
- Equipment failure
- Third party damage
- Incorrect operations
- Weather related and outside force
- Other threats

A Threat Assessment Workshop was conducted in Enbridge's offices in Duluth, Minnesota on December 9 and 10, 2015. The list of attendees at this workshop, along with their affiliations and job titles is provided in Table 4-2.

The objectives of the workshop were to review information from sources such as maps, imagery, design records, operating data, and the opinions of subject matter experts to meet the objectives of the analysis as outlined in Section 4.1.1.

During the workshop, standardized threat assessment forms were utilized to focus the discussion. Information from the workshop and from follow-up data collection exercises is presented in Section 4.1.5.

Table 4-2 Threat Assessment Workshop Attendees

Company	Name	Title

RPS Group	Matt Horn	Senior Scientist

4.1.5 Assessment of Threats

The attributes for each of the potential threats are discussed below.

4.1.5.1 External Metal Loss

External corrosion is a form of wall loss caused by interaction of the outside steel pipe surface with the environment. The primary form of defense against external corrosion is the external

corrosion coating on the pipe. Corrosion cannot occur so long as this coating is intact, and well-bonded to the surface of the pipe. In the event of a "holiday" (an area of missing coating), or disbondment of the coating from the surface of the pipe, the secondary defense is cathodic protection, which is designed to maintain the surface of the pipeline more electro-negative than its corrosion potential. Failure of both systems can lead to areas of localized wall loss caused by corrosion.

A summary of the threat assessment for external metal loss as it relates to L3RP is provided in Table 4-3 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

Table 4-3 External Metal Loss Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Coating Type	The following coating types will be used for L3RP: • Mainline pipe body coating system: Fusion Bond Epoxy (FBE) • Hot bends and field girth welds: 2-Part Liquid Epoxy • Horizonal Directional Drill (HDD) Sections: FBE with Abrasion-resistant overcoat Maximum temperature performance rating of all coatings is compatible with the 140°F maximum operating temperature.	All coating types being considered for the pipeline projects can be characterized as high-performance coating systems that form an efficient corrosion barrier, and that resist degradation with time.
Cathodic Protection	L3RP will have a remote-bed impressed cathodic protection (CP) system. Potential sources of interference such as High Voltage DC (HVDC) and High Voltage AC (HVAC) power lines, and adjacent pipelines will undergo testing to establish the most effective mitigation measures. If necessary, bonding will be completed to adjacent structures. Site-specific circumstances and plans are outlined below: • Site 1 – Mosquito Creek Crossing: – Additional existing lines parallel (4 Minnesota Pipe Line Company crude oil pipelines). Closest pipe 25 ft to L3RP – Interference testing will be completed. If necessary will bond to existing system – No potential AC interference • Site 2 – Mississippi River Crossing at Ball Club: – HVAC line running south of line which is currently mitigated for existing lines. – Great Lakes gas pipelines (2-3 lines) in vicinity but not parallel. Minimum separation distance would be 50 ft – Existing parallel Enbridge line (6 total) Min separation would be 25 ft (Enbridge Energy Partners [EEP]corridor) – Line would be bonded to EEP which fully mitigates existing lines. Site 3 – Sandy River Crossing: – No other existing lines (foreign or Enbridge-owned) – No sources of Interference (HVAC or HVDC) • Site 4 – Shell River Crossing: – Nearby overhead power line <300 ft HVDC – Far enough away that interference should not be an issue – No additional interference sources – No foreign pipelines	The proposed CP system design and testing measures represent industry best practice for cathodic protection systems.

Table 4-3 External Metal Loss Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
	• Site 5 – Red River Crossing: – 7 different parallel lines all Enbridge-owned min 25 ft separation. Plan is to bond to all 7 Lines at this location • Site 6 – Mississippi River Crossing at Palisade: – No adjacent pipelines – No foreign or Enbridge pipelines – No Sources of interference (HVAC or HVDC) • Site 7 – Mississippi River Crossing at Little Falls: – Viking parallel gas line will be minimum 50 ft away. – Testing for interference and appropriate mitigation such as bonding will be implemented if necessary	
CP Survey Plan	A Direct Current Voltage Gradient coating quality check will be completed on the L3RP following construction and within 18 months of commissioning. Annual test surveys to be completed on the L3RP. Additionally, close interval surveys will be completed every five years post construction. Rectifier readings will be completed on a minimum bi-monthly schedule. HDD sections will undergo coating quality testing after installation.	The proposed CP survey plans represent industry best practice for cathodic protection systems.
Soil Characteristics	No problematic conditions (acid rock drainage, high microbiological activity, etc.) have been identified along the L3RP.	There are no special concerns related to soil characteristics along L3RP.
Above-ground pipe	All piping within the scope of the analysis will be below-grade.	No consideration required for atmospheric corrosion or aeration cells.
Casings	There are no cased crossings within the scope of the analysis.	No consideration required for casing shorts.

Table 4-3 External Metal Loss Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Assessment Plan	Types of assessment to be performed, and assessment intervals to be used	Magnetic metal loss, ultrasonic crack detection, and high resolution geometry tool with an Inertial Mapping Unit as part of the baseline inspection will be completed within 1 year of in service. Inspection intervals will depend on previous findings, however currently planning 5 year inspection intervals for crack, corrosion and deformation tools. Features identified by in-line assessment tools will be evaluated against acceptability criteria, and those that exceed those criteria will be excavated and evaluated to assess the need for repair, replacement or recoating.
Analogue In Line Inspection (ILI) Data	During the Threat Assessment Workshop potential sources of Inline Inspection (ILI) data were discussed in consideration of: • Similar geographic region / terrain • Same CP standards and practices • Same coating systems • Reliability of ILI dataset • Preferably 15 years between installation date and inspection date	The following candidate ILI datasets were discussed in terms of their potential to provided suitable ILI analogues: • Line 64 – 2003 FBE – potential option • Line 4 in Canada – FBE Portions built in 90s and 2000s – follows same route as L3RP • To be provided

4.1.5.2 Internal Metal Loss

Internal metal loss is a form of degradation caused by corrosion, erosion, or a combination of the two. Internal corrosion is a form of wall loss caused by exposure of the inside surface of the pipe to an electrolyte (typically water). Internal corrosion may be enhanced by erosion, which is caused by sediment entrained within the product stream impinging against the internal surface of the pipe. Under extreme circumstances of sediment loading and product stream velocity, erosion can become a significant cause of metal loss without contributions from corrosion processes.

Internal corrosion can be eliminated by preventing water from coming into contact with the pipe surface. This can be achieved by eliminating water from the product stream and/or minimizing water content and maintaining turbulent flow conditions so as to keep water entrained within the product stream, thereby keeping it from coming into contact with the pipe surface. Erosion can be eliminated by maintaining the solid content of the product stream to low levels.

A summary of the threat assessment for internal metal loss as it relates to L3RP is provided in Table 4-4 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

Table 4-4 Internal Metal Loss Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Product Stream Characteristics	Tariffs for L3RP were reviewed, and elements of those tariffs that are relevant to internal corrosion are as follows: • L3RP Tariff FERC No. 41.10.0: – BS&W limited to 0.5%	A CEPA study (Penspen Integrity 2013) indicates that under normal operations, oil pipelines, including dilbit pipelines with low BS&W (0.25–0.5%) are unlikely to have free water present in them and, with a sufficiently high flow velocity inside the pipe, any free water presence caused by operation upsets will be entrained in the oil by turbulent flow, and the pipe wall will continue to be oil wetted. At low BS&W levels, in conjunction with turbulent flow, water will remain entrained in oil. Therefore, internal corrosion is unlikely to occur.
Product Stream Flow Characteristics	The products to be transported through the L3RP will be operated in such a manner as to maintain fully-turbulent and steady flow.	Turbulent flow controls solids deposition, and maintains what little water exists entrained in the product stream. The product stream, in conjunction with the operating and flow characteristics should render the pipe wall in an oil-wet (i.e., non-corrosive) condition, although monitoring and the implementation of appropriate mitigation strategies, where warranted, is required. Flow rates will be monitored to confirm turbulent flow, as well as no sediment or water drop-out.
Corrosion Detection Devices	Means of monitoring for internal corrosion	The use of internal coupons and in-line inspection will be employed to monitor for internal corrosion.
Receipt Points	L3RP will receive product from Clearbrook West and Superior receipt points.	Product is monitored to confirm that it meets Enbridge's tariff.
Chemical Inhibition Program	None planned	Monitoring and the implementation of appropriate mitigation strategies will be implemented, where warranted.
Cleaning Pig Program	None planned	

Table 4-4 Internal Metal Loss Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Assessment Plan	Types of assessment to be performed, and assessment intervals to be used	Magnetic metal loss, ultrasonic crack detection, and high resolution geometry tool with an Inertial Mapping Unit as part of the baseline inspection will be completed within one year of in service. Inspection intervals will depend on previous findings, however currently planning 5 year inspection intervals for crack, corrosion and deformation tools. Features identified by in-line assessment tools will be evaluated against acceptability criteria, and those that exceed those criteria will be excavated and evaluated to assess the need for repair, replacement or recoating.
Potential source of Analogue ILI Datasets	During the Threat Assessment Workshop potential sources of In-Line Inspection (ILI) data were discussed in consideration of: • Similar product type • Similar hydraulic regime • Similar continuity of flow • Similar inhibition and pigging program • Reliable ILI dataset • Preferably >15 years between installation date and inspection date	For liquid products, the important parameters that should be included in a comparison of corrosivity are water content, erosion and erosion/corrosion, flow velocity, flow mechanism, temperature, susceptibility to under-deposit corrosion (solid deposition, MIC potential, and water chemistry), and mitigation measures (use of inhibition, biocides, or pigging). To confirm that the corrosion mechanism and corrosivity that is represented by the analogue ILI dataset is representative of that which would be expected in the L3RP, an evaluation of all of these parameters were conducted. Through this process, it was determined that ILI data obtained from Enbridge's 36 inch Line 4 would be most representative of the corrosivity conditions expected on this pipeline.

4.1.5.3 Stress Corrosion Cracking

SCC in pipelines is a type of environmentally-assisted cracking (EAC). EAC is a generic term that describes the formation of cracks caused by various factors combined with the environment surrounding the pipeline. Together these factors reduce the pressure carrying capacity of the pipeline. When water (electrolyte) comes into contact with steel, the minerals, ions, and gases in the water can attack or corrode the steel. These chemical or electrochemical reactions may result in general wall thinning, corrosion pits, and/or cracks.

SCC involves corrosive mechanisms and depends on both an aggressive environment and tensile stress. SCC in pipelines is further characterized as "high pH SCC" or "near-neutral pH SCC," with the "pH" referring to the environment on the pipe surface at the crack location and not the soil pH. (pH is the measure of the relative acidity or alkalinity of water. It is defined as the negative log [base 10] of the hydrogen ion concentration. Water with a pH of 7 is neutral; lower pH levels indicate an increasing acidity, while pH levels above 7 indicate increasingly basic solutions). SCC flaw growth can be enhanced by pressure cycling and fatigue.

In terms of perspective relative to other threats, SCC is a relatively small causal factor for gas transmission pipeline incidents in the U.S., and SCC failures on hazardous liquid pipelines have been less frequent when compared with SCC occurrences on natural gas pipelines.

Based on industry experience, susceptibility to SCC has been associated with buried pipelines that have the following threat characteristics (Baker 2005):

- SCC susceptible coating system
- Pipe in operation greater than 10 years
- Operating stress levels greater than 60% Specified Minimum Yield Strength (SMYS)
- Located within 20 miles downstream of a pump station
- Temperatures greater than 100°F (specific to high-pH SCC)

SCC is found in areas of coating damage. Vintage coating systems (i.e., pre-FBE) are considered to be generally susceptible to the type of coating damage associated with SCC.

The use of effective, high-performance coatings for new pipeline design and installation is the most practical way preventing failures due to SCC in pipelines, and FBE, liquid epoxies, and urethanes are the preferred coatings for managing this threat.

A summary of the threat assessment for SCC as it relates to the L3RP is provided in Table 4-5 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

Table 4-5 Stress Corrosion Cracking Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
SCC Susceptibility	The following design and operating variables were reviewed for the L3RP: • Operating stress level – Max stress level 32.7% SMYS • Operating temperature – 140°F max • Distance from Pump Station – Minimum distance: 8 mi (Site 6) • Coating type – Mainline pipe body coating system: FBE; Hot bends and field girth welds: 2-Part Liquid Epoxy; HDD Sections: FBE with Abrasion-resistant overcoat	All the specified pipeline coating systems are characterized as high-performance coating systems, and as such, are resistant to the formation of significant SCC. To date, no operating company has ever experienced a failure that was attributed to SCC in a pipeline that was coated with these coating systems.
Pressure cycling and fatigue	A pressure cycling and fatigue study was conducted on L3RP (Enbridge 2015). This study concluded that fatigue life in this segment was deemed to be acceptable per the requirements of D02-110 (2013) - Fatigue Design of New Pipelines.	A Fatigue Life Analysis design process accounts for the type of pipe selected, the different pressure ranges encountered throughout the pressure cycles, and the operational parameters selected by the operator. The main purpose of these calculations is to aid operators in quickly avoiding unacceptable pressure cycling. This represents industry best practice, as it allows the operator to be aware of the threat environment, and to pre-emptively mitigate potential threats before they can manifest themselves as a failure.
Assessment Plan	Types of assessment to be performed, and assessment intervals to be used	Magnetic metal loss, ultrasonic crack detection, and high resolution geometry tool with an Inertial Mapping Unit as part of the baseline inspection will be completed within one year of in service. Inspection intervals will depend on previous findings. In addition, Enbridge is currently planning 5 year inspection intervals for crack, corrosion and deformation tools. Features identified by in-line assessment tools will be evaluated against acceptability criteria, and those that exceed those criteria will be excavated and evaluated to assess the need for repair, replacement or recoating.

4.1.5.4 Manufacturing Defects

Based on historical industry experience, manufacturing defects failures have been associated primarily with pipe seam defects and hard spots[7]. Other issues related to pipe manufacture such as out-of-roundness, out-of-dimensional-tolerance conditions in preparation of pipeline ends, and high hardenability[1] have contributed to field weldability[1] problems, which in themselves have constituted a threat.

In modern pipe manufacture, with the universal adoption of continuous casting in lieu of ingot casting practices, and with the advent of High Strength Low Allow (HSLA) steel designs, hard spots have been fully eliminated; however, for the most part, the remainder of the above-listed issues are still a concern. In addition, in recent years, hydrostatic test failures and dimensional out-of-spec conditions have resulted from the production of pipe that does not meet minimum yield strength criteria.

The best way to safeguard against manufacturing defect related pipeline failures is through the application of carefully designed and executed pipe manufacturing and quality control practices, as dictated by rigorous skelp and pipe mill pre-qualification procedures and pipe purchase specifications.

A summary of the threat assessment for manufacturing defects as it relates to the L3RP is provided in Table 4-6 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

[7] See Glossary

Table 4-6 Manufacturing Defects Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Manufacturing procedure specification	Manufacturing procedure specifications reviewed for pipe to be used on L3RP addresses: • Steelmaking • Slab and skelp manufacturing • Forming • Welding • Finishing • Hydrostatic testing • Inspection • Repair • Tracking and control • Laboratory testing • Quality management system • Material tracking system • Inspection and test plan • Non-conformances • Handling, shipping, storage • Third party inspection • Marking	The manufacturing procedure specification, together with the inspection and test plan constitute key quality assurance documents that form the basis of good pipe procurement practices.
Manufacturing Process	• All sites will use 36 in. Double Submerged Arc Welded (DSAW) straight-seam pipe.	While some vintage manufacturing processes are prone to manufacturing defects, modern line pipe manufacturing processes are not associated with characteristic chronic manufacturing defects. Well-developed manufacturing procedure specifications and inspection test plans are instrumental in maintaining quality assurance.
Use of Third Party Pipe Mill Auditors	• Roving auditors + final bench at pipe mills • Third party inspector during loading and unloading	While third party audits and inspection does not guarantee quality, the effective deployment of auditors promotes a quality focus during line pipe manufacture, while alerting purchasers to potential quality problems during manufacture and prior to delivery.
Line pipe manufacturer	• Site 1: 36 inch DSAW UOE line pipe	None of the pipe mills being used are associated with

Table 4-6 Manufacturing Defects Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
	manufactured by EVRAZ, Portland. • All other sites: 36 inch DSAW UOE line pipe manufactured by EVRAZ, Camrose	documented chronic quality problems.
Pressure cycling	• A pressure cycling and fatigue study was conducted on this segment of pipeline (Enbridge Pressure Cycling Analysis L3R 2015). This study concluded that fatigue life in this segment was deemed to be acceptable per the requirements of D02-110 (2013)—Fatigue Design of New Pipelines.	Fluctuating operating pressures, that are typical of liquids pipelines, can activate pre-existing manufacturing defects. Nevertheless, the Fatigue Life Analysis design process accounts for the type of pipe selected, the different pressure ranges encountered throughout the pressure cycles, and the operational parameters selected by the operator. The main purpose of these calculations is to aid operators in quickly avoiding unacceptable pressure cycling. This represents industry best practice, as it allows the operator to be aware of the threat environment, and to pre-emptively mitigate potential threats before they can manifest themselves as a failure.
Hydrostatic test	• A review was conducted of Enbridge Specification USPCS-Spec-Hydro-005 "Specification for Pipeline Construction (USA) Pipeline Hydrostatic Testing".	The L3RP pipeline will be tested to a maximum test pressure of 2003 psi. For the seven sites being evaluated, this test pressure ranges from 272% to 457% of maximum operating pressure. These represent significant safety factors, ensuring that any manufacturing defects left after the hydrostatic test are not operating at stress levels where they would be considered to be structurally significant.

4.1.5.5 Construction Defects

Historically, construction defect failures have been associated primarily with welding defects and installation defects such as dents and buckles, which may be associated with improper ditch preparation and backfill, or with the use of excessive tie-in strains. For a given pipe material, failures from construction defects are influenced by the following factors:

- Construction practices
- Joining practices
- Joint inspection practices
- Hydrostatic inspection practices
- Inspections
- Operating pressure

A summary of the threat assessment for construction defects as it relates to the L3RP is provided in Table 4-7 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

Table 4-7 Construction Defects Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Construction Practices	The following information related to construction practices proposed for L3RP were reviewed: • Welding processes: – Mechanized gas metal arc welding (GMAW)—mainline – Tie-ins—cellulosic root and hot pass with mechanized GMAW fill and cap – Weld zone assessment – 100% automated ultrasonic testing (AUT)/phased array – Potential for supplemental X-ray – Post-construction inspection – Caliper tool inspection – Post-construction pressure testing – Minimum test pressure 2003 psi Additionally, the Enbridge specification of Mainline Construction was reviewed, which addresses construction procedures related to activities such as trenching, lowering-in and backfilling.	Welding and non-destructive inspection procedures are representative of industry best practices, which maximize the use of low-hydrogen welding processes, and state-of-the-art inspection systems. Although construction specifications are comprehensive, leading to minimized potential for construction-related damage, such damage can occur, particularly on pipelines that have high diameter: wall thickness ratio. Post-construction in-line inspection is an effective measure of identifying such damage, and enabling repairs to be made before defects can grow to failure during operation. For the 7 modeling locations being evaluated along the L3RP pipeline, hydrostatic test pressure ranges from 272% to 457% of maximum operating pressure. These represent important safety factors, and help confirm that any construction defects left after the hydrostatic test are not operating at stress levels where they would be considered to be structurally significant.
Operating Pressure	• A pressure cycling and fatigue study was conducted on this segment of pipeline (Enbridge Pressure Cycling Analysis L3R, 2015). This study concluded that fatigue life in this segment was deemed to be acceptable per the requirements of D02-110 (2013) - Fatigue Design of New Pipelines.	Fluctuating operating pressures that are typical of liquids pipelines can activate pre-existing construction defects. Nevertheless, the Fatigue Life Analysis design process accounts for the type of pipe selected, the different pressure ranges encountered throughout the pressure cycles, and the operational parameters selected by the operator. The main purpose of these calculations is to prevent unacceptable pressure cycling at the earliest stages possible. This represents industry best practice, as it allows the operator to be aware of the threat environment, and to pre-emptively mitigate potential threats before they can manifest themselves as a failure.

4.1.5.6 Equipment Failure

Equipment failure is defined in the context of pipeline transmission infrastructure as failures occurring in pressure retaining components other than pipe and fittings such as valves, flanges, and gaskets. These components require the same types of quality surveillance and inspection as the pipe itself. Risk factors for equipment failure are related to operating and maintenance (O&M) procedures, and the quality management systems that detail when and how inspections and maintenance of equipment will be performed and what specific action is required.

As the pipeline segments associated with each of the seven modeling locations does not include non-pipe equipment, this threat was determined to be out of scope for this assessment.

4.1.5.7 Third Party Damage

Third party damage is defined as third-party-inflicted damage, typically caused by ground disturbance by heavy equipment, such as excavators. All pipelines experience some level of threat due to third party damage. The magnitude of this threat is a function of the effectiveness of damage prevention measures, adjacent land use and depth of cover, as well as damage resistance characteristics of the pipe. Although damage prevention measures can help to offset this threat, third party damage can never be fully neutralized. In this respect, failure susceptibility due to third party damage can be established as the product of two independent variables; the frequency of incurring a hit and the probability of failure given such a hit.

Impact frequency due to external interference has been characterized in terms of damage prevention factors; specifically (Chen and Nessim 1999a):

- Adjacent land use
- One-call system availability and promotion
- Signage placement
- Use of buried marker tape
- Response time for locate requests
- Patrol frequency
- Marking and locating methods
- Depth of cover

A summary of the threat assessment for third party damage as it relates to the L3RP is provided in Table 4-8 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

Table 4-8 Third Party Damage Threat Attribute Summary

Threat Attribute	Data Evaluation	Threat Considerations
Adjacent land use	For the purposes of evaluating exposure to accidental interference, Chen and Nessim (1999) characterizes adjacent land use as commercial / industrial / high density residential / low density residential / agricultural / remote	Enbridge's damage prevention measures are representative of industry best-practice. Nevertheless, the potential for third party damage cannot be discounted.
One-call system availability and promotion	The one-call promotion practice to be employed on L3RP includes the promotion and use of an 811 call number, community involvement, and community meetings.	
Signage placement	The signage placement practice to be adopted on L3RP includes warning signs at road, railways, water crossing, both sides of pipeline, irrigation, areas where third party might occur, fence crossings, and areas of population growth (i.e., all crossings plus areas of potential activity). Sign placement also takes into account line of sight and potential activity.	
Use of buried marker tape	Buried marker tape is not used, and is not relevant to HDD crossings.	
Response time for locate requests	The response time standard for locate requests within Minnesota is within two business days.	
Patrol frequency	Patrol frequency is 26 times per year but not exceeding every 3 weeks (helicopter and fixed wing)	
Marking and locating methods	The marking and location practices to be employed on L3RP are as follows: • Excavations within 100 ft: locate and mark • Excavations within 16 ft: expose by vacuum truck • Excavations within 2 ft: expose by hand digging	
Depth of cover	All HDD installations have a minimum cover of 40 ft All trenched installations have a minimum cover of 4 ft (3 ft in rock ditch).	

4.1.5.8 Incorrect Operations

Incorrect operations failure is defined in the context of pipeline transmission infrastructure as failures that have causal factors that are related to design, as well as operation and maintenance procedures. A review of these procedures as they relate to the L3RP was evaluated by means of an Operations Questionnaire which was completed by workshop attendees during the threat assessment workshop. Results of the questionnaire are summarized below.

The threat environment associated with this threat is best evaluated through dialogue that is focused on design and operational factors related to the following attributes:

- Design attributes
  - Hazard identification
  - Maximum Allowable Operating Pressure (MAOP) potential
  - Safety systems
  - Checks
- Operations attributes
  - Operating procedures
  - Management of change procedures
  - Supervisory Control and Data Acquisition (SCADA) / communications
  - Drug testing procedures
  - Safety programs
  - Surveys / maps / records
  - Training procedures and programs
  - Mechanical error preventers

To facilitate the collection of information related to the above, an Operations Questionnaire, focused on the above attributes was administrated during the Threat Assessment Workshop. This questionnaire, along with the results of the targeted discussion associated with each of the attributes, is reproduced in Table 4-9.

Table 4-9 Operations Questionnaire

Contents

Section	Subject	Title	Questions	Possible Points
1.1	Design	Hazard Identification	4	4
1.2		MAOP Potential	1	12
1.3		Safety Systems	1	10
1.4		Material Selection	2	2
1.5		Checks	1	2
2.1	Operations	Operating Procedures	7	7
2.2		Management of Change	7	7
2.3		SCADA/Communications	1	3
2.4		Drug Testing	2	2
2.5		Safety Programs	1	2
2.6		Surveys/Maps/Records	2	5
2.7		Training	10	10
2.8		Mechanical Error Preventers	4	7
		Total	43	73

NOTES:

Survey questions for all topics other than Management of Change were based on the Incorrect Operations approach contained in *Pipeline Risk Management Manual*, Third Edition [Muhlbauer, W.K.]. Management of Change approach was based on API RP 581 Part 2 "Risk Based Inspection Technology" – Annex 2.A – Management Systems Workbook.

Scores are assigned such that higher scores are associated with the most favorable response.

Table 4-9 Operations Questionnaire

Question #	Question	Possible Score	Actual Score
1. Design			
1.1	Hazard Identification		
	a. Has a threat assessment been performed that entertains all possible threats?	1	1
	b. Do the results of the threat assessment reflect current conditions?	1	1
	c. Have possible hazards and risks associated with the work been identified through studies such as HAZOP, risk assessment, or reliability analysis?	1	1
	d. Are the results of the above studies available in documented form?	1	1
	Section Totals	***4***	***4***
1.2	MAOP Potential		
	Characterize the ease with which MAOP could be reached on the pipeline system (select one response only):		
	a. Routine. Routine, normal operations could allow the system to reach MAOP. Overpressure would occur fairly rapidly due to incompressible fluid or rapid introduction of relatively high volumes of compressible fluids. Overpressure is prevented only by procedure or single-level safety device.	0	
	b. Unlikely. Overpressure can occur through a combination of procedural errors or omissions, and failure of safety devices (at least two levels of safety).	5	
	c. Extremely Unlikely. Overpressure is theoretically possible (sufficient source pressure), but only through an extremely unlikely chain of events including errors, omissions, and safety device failures at more than two levels of redundancy.	10	10
	d. Impossible. Overpressure cannot occur, under any conceivable chain of events.	12	
	Section Totals	***12***	***10***

Table 4-9 Operations Questionnaire

Question #	Question	Possible Score	Actual Score
1.3	Safety Systems		
	Describe the safety systems that are in place (select one response only):		
	a. No Safety Devices Present. No safety devices are present to prevent overpressure.	0	
	b. On Site, One Level. A single on-site device offers protection from overpressure.	3	
	c. On Site, ≥2 Levels. Two or more independent on-site devices offer protection from overpressure.	6	5*
	d. Remote, Observation Only. Pressure is monitored from a remote location. Remote control is not possible, and automatic overpressure protection is not present.	1	
	e. Remote, Observation and Control. Pressure is monitored from a remote location. Remote control is possible, and automatic overpressure protection is not present.	3	
	f. Non-Owned, Active Witnessing. Overpressure prevention devices exist, but are not owned, maintained, or controlled by the owner of the equipment that is being protected. The owner takes steps to ensure that the safety device(s) is properly calibrated and maintained by witnessing such activities.	-2	
	g. Non-Owned, No Involvement. Overpressure prevention devices exist, but are not owned, maintained, or controlled by the owner of the equipment that is being protected. The owner does not take steps to ensure that the safety device(s) is properly calibrated and maintained by witnessing such activities.	-3	
	h. Safety Systems Not Needed. Safety systems not needed because overpressure cannot occur.	10	
	Section Totals	***10***	***5***
1.4	Materials Selection		
	Are design documents available that illustrate that all piping systems were designed with consideration given to all anticipated stresses?	1	1
	Do control documents, including material specifications and design drawings for all systems and components exist and maintained in an up-to-date manner?	1	1
	Section Totals	***2***	***2***
1.5	Checks		
	Do procedures exist that require design calculations and decisions to be checked by a licensed professional	2	1

* Less than full marks awarded reflecting less than complete independence of overpressure protection.

Table 4-9 Operations Questionnaire

Question #	Question	Possible Score	Actual Score
	engineer at key points during the design process?		
	Section Totals	2	1
2. Operation			
2.1	Operating Procedures		
	Do written procedures covering all aspects of pipeline operation exist?	1	1
	Are these procedures actively used, reviewed, and revised?	1	1
	Are copies of these procedures available at field locations?	1	1
	Does a protocol exist that specifies the responsibility for procedure development and approval?	1	1
	Does a protocol exist that specifies how training is performed against these procedures?	1	1
	Does a protocol exist that specifies how compliance to these procedures is verified?	1	1
	Does a document management system exist that ensures version control, and proper access to the most current procedure documents?	1	1
	Section Totals	7	7
2.2	Management of Change		
	Is there a written MOC procedure that must be followed whenever processes, procedures or physical assets are changed?	1	1
	Are authorization procedures clearly stated and at an appropriate level?	1	1
	Do physical changes, changes in operating conditions, and changes in operating procedures invoke the MOC procedure?	1	1
	Is there a clear understanding of what constitutes a 'temporary change', and does the MOC procedure address temporary changes?	1	1
	Are temporary changes tracked to ensure that they are either removed after a reasonable period of time or reclassified as permanent?	1	1
	Do the MOC procedures specifically require the following actions whenever a change is made to an operating procedure?	1	1
	Update all affected operating procedures		
	Update all affected maintenance programs and inspection schedules		

Table 4-9 Operations Questionnaire

Question #	Question	Possible Score	Actual Score
	Modify drawings, statement of operating limits, and any other safety information affected?		
	Notify all operations and maintenance employees who work in the area of the change, and provide training as required		
	Review the effect of the proposed change on all separate but interrelated procedures		
	When changes are made in operating procedures, are there written procedures requiring that the impact of these changes on the equipment and materials of construction be reviewed to determine whether they will cause any increased rate of deterioration or failure, or will result in different failure mechanisms in the equipment?	1	1
	Section Totals	7	7
2.3	SCADA / Communications		
	Describe the SCADA / Communications systems that are in place (select one response only):		
	a. Level 1. No SCADA system exists, or is not used in a manner that promotes human error reduction.	0	
	b. Level 2. Some critical activities are monitored; field actions are informally coordinated through a control room; system is at least 80% operational.	1	
	c. Level 3. Most critical activities are monitored; field actions are usually coordinated through a control room; system up-time exceeds 95%.	2	
	d. Level 4. All critical activities are monitored; all field actions are coordinated through a control room; SCADA system reliability (measured in up-time) exceeds 99.9%.	3	3
	Section Totals	3	3
2.4	Drug Testing		
	Does a drug testing program exist that applies to employees who play substantial roles in pipeline operations?	1	1
	Does the testing program incorporate elements of random testing, testing for cause, pre-employment testing, post-accident testing, and return-to-work testing?	1	1
	Section Totals	2	2
2.5	Safety Programs		
	Does the company's safety program incorporate the following elements? (award partial marks for compliance with only a portion of the elements):	2	2
	Written company statement of safety philosophy		

Table 4-9 Operations Questionnaire

Question #	Question	Possible Score	Actual Score
	Safety program designed with high level of employee participation		
	Strong safety performance record		
	Good attention to housekeeping		
	Signs, slogans, etc. to show an environment tuned to safety		
	Full-time safety personnel		
	Section Totals	***2***	***2***
2.6	Surveys, Maps, Records		
	Are surveys such as those listed below conducted on a regular basis? (award partial marks for compliance with only a portion of the elements):	3	3
	Close interval pipe-soil surveys		
	Coating condition surveys		
	Water crossing surveys		
	In Line Inspection (ILI) assessments		
	Population density surveys		
	Depth of cover surveys		
	Leak detection surveys		
	Patrols (aerial or ground-based)		
	Are detailed, clear maps and records updated regularly, and are they available to all operations staff?	2	2
	Section Totals	***5***	***5***
2.7	Training		
	Evaluate the operator training program in terms of the following elements:		
	a. Minimum training requirements are documented	2	2
	b. Incorporates testing	2	2
	c. Covers the following:		
	i. Product characteristics	0.5	0.5

Table 4-9 Operations Questionnaire

Total Points		**73**	**65**

4.1.5.9 Geotechnical / Hydrotechnical Forces

This threat category is associated with outside forces associated with geophysical factors that can act on a pipeline. These outside forces can be caused by earth movement, erosion / water impingement, rock fall, flooding, etc. The primary means of preventing outside forces associated with these factors is to identify and avoid the area of potential geotechnical or Hydrotechnical activity.

The assessment of geotechnical and hydrotechnical threats involved a separate detailed study in which all information relevant to each site was integrated and evaluated. The report describing the process and findings is summarized in Attachment A.

4.1.5.10 Other Threats

During the Threat Assessment Workshop, an open discussion was held to identify potential threat mechanisms that do not fall into one of the nine categories listed in Section 4.1.4. A wide variety of operating threats were discussed, including forest fires, concomitant failures, access restrictions, and exposure to vandalism.

A summary of the threat assessment for other defects as it relates to the L3RP is provided in Table 4-10 (note that the Threat Attributes identified in this Table are those factors that influence both the causal and mitigation factors within the threat environment).

Table 4-10 Other Threats Threat Attribute Summary

<table>
<tr><th>Threat Attribute</th><th>Data Evaluation</th><th>Discussion of Threat Potential</th></tr>
<tr><td>Concomitant Failures</td><td>Concomitant failures occur where the catastrophic failure of one pipe (typically a natural gas pipe, in which rapid decompression of a compressible fluid results in the formation of a large blast crater, and in which the ensuing release of natural gas is readily ignitable), can result in the uncovering of an adjacent pipe, which may become involved in an ensuing fire.
Design considerations to address the potential for concomitant failure are addressed in Clause 4.11.6 of CSA Z662-11, which references criteria outlined in IGEM/TD/1. This Standard provides safe separation distance to existing gas pipelines as a function of diameter and soil conditions. The maximum safe separation distance published by this standard is associated with 48-inch diameter gas pipelines operating at pressures up to 1160 psi, and is listed as 12 m (39.4 ft).</td><td>A review of spacing between existing pipeline infrastructure (if any) was conducted at each site, and is summarized below:
<table><tr><th>Site No.</th><th>Adjacent Pipeline Considerations</th></tr><tr><td>1</td><td>Existing Minnesota Pipe Line Company oil pipelines with minimum 25 ft separation to L3R. Concomitant failure not considered to be a threat.</td></tr><tr><td>2</td><td>Great Lakes gas pipelines in vicinity will have minimum separation distance of 50 ft This meets the safe separation requirements of IGEM/TD/1. Existing Enbridge oil pipelines (6 in total) with minimum separation distance of 25 ft Concomitant failure not considered to be a threat.</td></tr><tr><td>3</td><td>No adjacent parallel pipelines.</td></tr><tr><td>4</td><td>No adjacent parallel pipelines.</td></tr><tr><td>5</td><td>7 separate LVP liquids pipelines with minimum separation distance of 25 ft Concomitant failure not considered to be a threat.</td></tr><tr><td>6</td><td>No adjacent parallel pipelines.</td></tr><tr><td>7</td><td>Parallel Viking gas pipeline will have minimum separation distance of 50 ft This meets the safe separation requirements of IGEM/TD/1.</td></tr></table></td></tr>
<tr><td>Access</td><td>Presence of segments where accessibility constraints</td><td>None such access restrictions were identified.</td></tr>
</table>

Table 4-10 Other Threats Threat Attribute Summary

Threat Attribute	Data Evaluation	Discussion of Threat Potential
Restrictions	(whether due to landowner relations or physical) are such that they act as a barrier to regular pipeline maintenance activities, such as corrosion surveys, defect excavations, etc.	
Forest fires	With respect to forest fires, experience dictates that where a pipe is buried in a cleared ROW, forest fires do not constitute a significant loss-of-containment hazard in and of themselves, since the ROW acts as a fire break, and the ground cover acts to insulate the pipe.	Industry experience indicates that forest fires are not a threat for buried pipelines. There are no above-ground sections of pipeline on L3RP, except in the immediate vicinity of pump stations and valves.
Exposure to Vandalism	Exposure to vandalism is greatest at above-ground facilities, where measures such as fenced compounds and locks are installed.	There are no above-ground sections of pipeline within the scope of work.

4.1.6 Threat Potential Summary

In this Section, a summary of threat potential is provided based on a review and analysis of the information contained in Section 4.1.5. Additionally, based on the available data for each threat, this Section provides overviews of appropriate approaches for estimating failure likelihood. A detailed description of the failure frequency estimation approach for each threat is provided in Section 4.2.

Where appropriate, assumptions that will be incorporated into the quantitative failure analysis are identified for each threat.

4.1.6.1 External Metal Loss

4.1.6.1.1 Threat Potential

It is expected that the pipeline will have some degree of exposure to the threat of external corrosion. Therefore, the threat potential for external corrosion was included in the quantitative failure frequency estimate.

4.1.6.1.2 Approach

As will be discussed in greater detail in Section 4.2.3.1, reliability approaches for providing quantitative estimates of failure likelihood exist for some threats, including corrosion. Reliability approaches have the benefit of accounting for design and material performance characteristics. In addition, for time-dependent threats such as corrosion, they accurately reflect that failure likelihood changes with time.

For the external metal loss threat, a reliability approach was used that leverages existing "analogue" ILI datasets, along with the specific design details (diameter, wall thickness, grade, operating pressure) of the L3RP at each site of interest. With this approach, it is important to confirm that the analogue datasets are representative (or slightly conservative) relative to the expected external corrosion performance of the proposed pipeline segments. In this way, the reliability parameters from the analogue ILI datasets for external corrosion feature incident rate, external corrosion feature size distribution, and external corrosion growth rate will be representative, or conservative relative the same parameters for the L3RP. To ensure that this is the case, the considerations outlined in Table 4-11 were incorporated into the assessment.

Table 4-11 Considerations for Quantitative Failure Likelihood Estimates—External Corrosion

Threat Factor	Issue	Controls	Action
Mainline Coating Type	The mainline external coating system used in the pipeline from which the analogue ILI data are taken should be representative or conservative, relative to the expected corrosion coating performance on the L3RP.	Analogue ILI datasets that are representative of FBE coating systems will address this issue.	To be addressed during selection of analogue ILI dataset
Field Joint Coating	The field joint external coating system used in the pipeline from which the analogue ILI data are taken should be representative or conservative, relative to the expected corrosion coating performance on the L3RP.	Analogue ILI datasets that are representative of high performance field joint coating systems will address this issue.	To be addressed during selection of analogue ILI dataset
Temperature effects on external coatings	Operating temperatures that exceed the maximum temperature rating of the mainline and field joint coating systems can result in significantly degraded coating performance over time	Coating systems are being specified for mainline and field girth welds are rated to withstand the expected maximum operating temperatures of the L3RP	Addressed by purchase specifications and detailed design
		Analogue ILI datasets must be selected so that they are representative of pipelines that have not been operated above the maximum temperature rating of either the mainline or field girth weld coating systems.	To be addressed during selection of analogue ILI dataset
Cathodic Protection	Ensure that CP performance in pipeline from which analogue ILI dataset is obtained is representative of CP performance expected on the L3RP.	Design measures for L3RP incorporate identification of potential sources of interference, and incorporation of appropriate mitigations	Addressed by L3RP detailed design, and in operating procedures.
		Analogue ILI datasets must be selected so that they are representative of CP design and operating practices for L3RP.	To be addressed during selection of analogue ILI dataset

Table 4-11 Considerations for Quantitative Failure Likelihood Estimates—External Corrosion

Threat Factor	Issue	Controls	Action
Soil Characteristics	Ensure that soil characteristics in pipeline from which analogue ILI dataset is obtained is representative of soil characteristics on the L3RP.	Identify any locations of highly corrosive ground conditions on L3RP, such as acid-generating rock. If present, ensure that analogue ILI dataset is representative of similar conditions.	Undertaken during threat assessment – no such highly corrosive ground conditions identified.
ILI Data	Potential for manufacturing defects to be misinterpreted as corrosion defects, leading to unrealistically high corrosion feature incidence rates and aggressive apparent growth rate distributions	Utilize a dataset from a pipeline that is old enough to mask the effects of manufacturing defects.	To be addressed during selection of analogue ILI dataset

4.1.6.2 Internal Metal Loss

4.1.6.2.1 Threat Potential

The corrosivity analysis contained in Section 4.1.5.2 indicated that the product stream in conjunction with the operating and flow characteristics should render the pipe wall in an oil-wet (i.e., non-corrosive) condition, although ongoing monitoring with a view to implementing appropriate mitigation strategies is warranted. While the threat of internal corrosion is not anticipated to be a significant contributor to overall failure likelihood for the L3RP, it is not possible to disqualify this threat entirely.

4.1.6.2.2 Approach

As will be discussed in greater detail in Section 4.2.3.1, reliability approaches for providing quantitative estimates of failure likelihood exist for some threats, including corrosion. Reliability approaches have the benefit of accounting for design and material performance characteristics. In addition, for time-dependent threats such as corrosion, they accurately reflect that failure likelihood changes with time.

For the internal metal loss threat, a reliability approach was used that leverages existing "analogue" ILI datasets along with the specific design details (diameter, wall thickness, grade, operating pressure) of the L3RP at each site of interest. Under such an approach it is important to confirm that the analogue datasets are representative (or slightly conservative) relative to the expected internal corrosion performance of the proposed pipeline segments. In this way, the reliability parameters from the analogue ILI datasets for internal corrosion feature incident rate, internal corrosion feature size distribution, and internal corrosion growth rate will be representative, or conservative relative the same parameters for the L3RP. To ensure that this is the case, the considerations outlined in Table 4-12 were incorporated into the assessment.

Table 4-12 Considerations for Quantitative Failure Likelihood Estimates—Internal Corrosion

Threat Factor	Issue	Controls	Action
Water Content	Elevated water content can result in stratification in some flow regimes, and may result in enhanced corrosivity	• Control BS&W to 0.5% max, reflecting standards for transmission pipelines. • Maintain turbulent flow to entrain what little water that exists in the product stream flow, causing pipe wall to remain in oil-wet condition.	• 0.5% BS&W reflects current tariff specifications. • Hydraulic design of L3RP ensures turbulent flow. • Flow rates will be monitored to ensure turbulent flow, and to ensure that no sediment or water drop-out occurs
		Ensure that BS&W and hydraulic flow regime in pipeline from which analogue ILI dataset is obtained is representative of conditions in L3RP.	To be addressed during selection of analogue ILI dataset
Deposit of Solids	Solid deposition can result in under-deposit corrosion	• Control BS&W to 0.5% max, reflecting standards for transmission pipelines. • Maintain turbulent flow to entrain what little solids that exists in the product stream, and to prevent deposition of solids	• 0.5% BS&W reflects current tariff specifications. • Hydraulic design of L3RP ensures turbulent flow. • Flow rates will be monitored to ensure turbulent flow, and to ensure that no sediment or water drop-out occurs
		Ensure that BS&W and hydraulic flow regime in pipeline from which analogue ILI dataset is obtained is representative of conditions in L3RP.	To be addressed during selection of analogue ILI dataset
Corrosion Monitoring	Regardless of interpreted susceptibility to corrosion based on product composition and flow characteristics, monitoring is required to ensure that the pipeline remains in a condition that is not susceptible to internal corrosion.	Corrosion detection devices	• The use of internal coupons and in-line inspection will be employed to monitor for internal corrosion. • Flow rates will be monitored to ensure turbulent flow, and to ensure that no sediment or water drop-out occurs
ILI Data	Potential for manufacturing defects	Utilize a dataset from a pipeline that is old	To be addressed during selection of

Table 4-12 Considerations for Quantitative Failure Likelihood Estimates—Internal Corrosion

Threat Factor	Issue	Controls	Action
	to be misinterpreted as corrosion defects, leading to unrealistically high corrosion feature incidence rates and aggressive apparent growth rate distributions	enough to mask the effects of manufacturing defects.	analogue ILI dataset

4.1.6.3 Stress Corrosion Cracking

4.1.6.3.1 Threat Potential

Based on industry experience, susceptibility to SCC has been associated with coatings other than the following:

- FBE
- Urethane and liquid epoxy
- Extruded polyethylene
- Multi-layer or composite coatings

The threat potential for SCC is anticipated to be negligible (i.e., this threat will not contribute in a substantial way to overall failure likelihood), since the coating systems used on the L3RP are limited to those listed above.

4.1.6.4 Manufacturing Defects

4.1.6.4.1 Threat Potential

Enbridge's pipe procurement program specifies rigorous controls to confirm the quality of line pipe to be supplied to the L3RP Project. Although line pipe for LVP pipelines is not required to have proven notch toughness, pipe with minimum notch toughness values of 29.5 ft-lbs (40 J) will be used. Additional controls will be implemented that include supplier pre-qualification practices that focus on technical and quality criteria, as well as third party pipe mill quality surveillance. While the threat of manufacturing defects is not anticipated to be a significant contributor to overall failure likelihood for the L3RP, it is not possible to disqualify this threat entirely.

4.1.6.4.2 Approach

The threat of manufacturing defects does not lend itself to failure likelihood estimation using a reliability approach due to the lack of a limit state model that is supported by probability distributions for its input parameters (Section 4.2.3). Despite the fact that this threat is not anticipated to contribute significantly to overall failure likelihood, an attempt will be made to achieve an estimate of failure frequency based on industry operating experience of recent installations of hazardous liquids pipelines.

4.1.6.5 Construction Defects

4.1.6.5.1 Threat Potential

Enbridge's construction practices that will be used in the construction of the L3RP Project specifies rigorous controls to confirm the quality of the pipeline installation, including welding processes. In addition, quality checks will be employed, including 100% NDT using phased array ultrasonics and/or X-ray inspection, as well as 100% inspection with a pipe size and deformation tool after installation to confirm that the pipeline is free of dents, buckles, and excessive out-of-round conditions. The use of a mechanized low hydrogen welding process, in which procedural

variables are tightly controlled, is an effective means of maintaining weld quality and procedural control.

While the threat of construction defects is not anticipated to be a significant contributor to overall risk for the L3RP, it is not possible to disqualify this threat entirely.

4.1.6.5.2 Approach

The threat of construction defects does not lend itself to failure likelihood estimation using a reliability approach due to the lack of a limit state model that is supported by probability distributions for its input parameters (Section 4.2.3). Despite the fact that this threat is not anticipated to contribute significantly to overall failure likelihood, an attempt will be made to achieve an estimate of failure frequency based on industry operating experience of recent installations of hazardous liquids pipelines.

4.1.6.6 Equipment Failure

As the pipeline segments associated with each of the seven modeling locations do not include non-pipe equipment, this threat was determined to be out of scope for this assessment.

4.1.6.7 Third Party Damage

4.1.6.7.1 Threat Potential

All pipelines experience some level of threat due to third party damage, the magnitude of this threat being a function of the effectiveness of damage prevention measures, adjacent land use, depth of cover, material properties, and pipeline design. Although damage prevention measures can help to offset this threat, third party damage can never be fully neutralized, and so this is expected to be one of the primary threats in contributing to overall pipeline failure likelihood.

4.1.6.7.2 Approach

A reliability model exists that considers all the parameters of damage prevention measures, adjacent land use, depth of cover, material properties and pipeline design; this model will be used in the failure frequency analysis (Section 4.2) (Chen and Nessim 1999). The reliability approach employs a fault tree model to estimate hit frequency, and a separate stochastic model to predict probability of failure, given a hit.

4.1.6.8 Incorrect Operations

4.1.6.8.1 Threat Potential

All pipelines experience some level of threat due to incorrect operations, the magnitude of this threat being a function of the effectiveness of design-related and operations/maintenance related practices and measures. Although design, operations and maintenance practices can help to offset this threat, incorrect operations can never be fully neutralized, and so this is expected to be one of the primary threats in contributing to overall failure likelihood.

4.1.6.8.2 Approach

The threat of incorrect operations does not lend itself to failure likelihood estimation using a reliability approach due to the lack of a limit state model that is supported by probability distributions for its input parameters (Section 4.2.3). Reflecting this fact, an attempt will be made to achieve an estimate of failure frequency based on operating incident data, related to this threat, modified by the results of the Operations Questionnaire that was administered during the Threat Assessment Workshop (Table 4-9).

4.1.6.9 Geotechnical / Hydrotechnical Forces

To assess the degree of threat that a pipeline will be exposed to, a thorough evaluation of information related to the potential for geotechnical and hydrotechnical threats was undertaken at each of the seven modeling locations within the scope of work. A description of the threat potential and the approach by which estimates of failure likelihood were derived is provided in Attachment A.

4.1.6.10 Other Threats

During the Threat Assessment Workshop, an open discussion was held to identify potential threat mechanisms that do not fall into one of the nine categories listed above. The following potential threats were reviewed:

- Potential for concomitant failure associated with adjacent pipelines
- Access restrictions
- Forest fires
- Exposure to vandalism

As discussed in Section 4.1.5.10, none of the "Other Threats" were found to represent significant potential for failure.

4.2 QUANTITATIVE FREQUENCY ANALYSIS

4.2.1 Overview and Summary

To be consistent with the assessment of full bore ruptures in the consequence analysis, the frequency analysis focused on the occurrence of ruptures (as opposed to smaller leaks). Based on the guidance provided in the Threat Assessment, the frequency analysis undertook to estimate rupture frequency using optimal approaches for each threat. These approaches included:

- Methods based on Industry Incident Data—PHMSA Hazardous Liquids Database, 2010–2015 (threats assessed using this method included manufacturing defects, construction defects and incorrect operations)
- Methods based on mechanistic, reliability approaches (external corrosion, internal corrosion, and third party damage)

- Site-specific evaluation of hydrotechnical and geotechnical hazards (weather related and outside forces)

The annual probability of a large oil release (i.e., a full bore rupture) was determined for each of the seven modeling locations for L3RP. The length of the pipeline segment that was considered in the failure frequency analysis for each modeling site was established through outflow and overland spill modeling of full-bore rupture release scenarios for the modeling site. Specifically, the failure frequency analysis for the site considered the length of pipeline around the site of the hypothetical full bore rupture from which a crude oil release could affect (i.e., reach) the immediately adjacent waterbody through direct release or overland flow.

The annual probability values, as well as the average annual return periods (defined as the inverse of the annual probability values) at each modeling site are summarized in Table 4-13.

Table 4-13 Annual Probability of Rupture and Average Return Period within the Potential Impact Segment of Each of the Seven Modeling locations

Site Number	Annual Probability of Rupture	Average Return Period (yr)
1—Mosquito Creek	3.402×10^{-06}	293,945
2—Mississippi River at Ball Club	3.961×10^{-07}	2,524,615
3—Sandy River	1.939×10^{-06}	515,730
4—Shell River	4.388×10^{-06}	227,894
5—Red River	2.781×10^{-06}	359,583
6—Mississippi River at Palisades	2.527×10^{-06}	395,726
7—Mississippi River at Little Falls	2.287×10^{-06}	437,254

Of note, for linear infrastructure, such as pipelines, the probability of incurring a failure is proportional to segment length (i.e., the longer the segment that is being considered, the greater is the likelihood of incurring a failure at some point along that segment). This is reflected in the above results, with the longest potential impact segment (the 2,543 ft-long segment associated with the Shell River crossing), having the greatest probability of failure.

The likelihood of a large oil release occurring ranges from 3.96×10^{-07} to 4.39×10^{-06}; this is equivalent to average annual return periods that range from 227,894–2,524,615 years.

4.2.2 Introduction

This Section describes the approach and the results of a quantitative failure frequency assessment at seven modeling locations along the L3RP pipeline:

- Site 1—Mosquito Creek Crossing
- Site 2—Crossing of the Mississippi River at Ball Club

- Site 3—Sandy River Crossing
- Site 4—Shell River Crossing
- Site 5—Red River Crossing
- Site 6—Crossing of the Mississippi River at Palisades
- Site 7—Crossing of the Mississippi River at Little Falls

As described in the Threat Assessment (Section 4.1), seven threats were identified, and are addressed by the quantitative failure frequency analysis contained in this Section:

- External corrosion
- Internal corrosion
- Third party damage
- Manufacturing defects
- Construction defects
- Incorrect operations
- Geotechnical / hydrological forces

In the remainder of this chapter, the approach used to complete the failure frequency analysis is first described. Results of the failure frequency analysis are then described.

4.2.3 Failure Frequency Approach

For the purposes of the failure frequency analysis described here, the term "failure" refers to loss-of-containment of the L3RP pipeline. To be consistent with the assessment of full bore ruptures in the consequence analysis, the frequency analysis focused on the occurrence of ruptures (as opposed to smaller leaks).

In the following section of this chapter, quantitative estimates of annual failure probability for a full bore rupture were determined on a threat-by-threat basis. As was discussed in the Threat Assessment (Section 4.1), the most appropriate method for estimating failure frequency was identified for each threat, taking into account the type and availability of data, and the methods available that are applicable to failure estimation for each threat.

4.2.3.1 Quantitative Approach for Estimating Failure Frequency

As outlined below, there are a variety of approaches for making quantitative estimates of pipeline failure likelihood. One method is to use industry incident statistics as the basis for the making the estimate. Another method is to estimate failure likelihood based on a first-principles approach, known as "reliability methods". A third method, specific to the estimation of failure frequency related to geohazards, employs an approach that expresses the frequency of loss of containment as the product of the potential for the geohazard to occur, the frequency of occurrence, the unmitigated system vulnerability, and the effects of the mitigations used in the segment.

LINE 3 REPLACEMENT PROJECT:
ASSESSMENT OF ACCIDENTAL RELEASES: TECHNICAL REPORT

Pipeline Failure Probability Analysis
January 13, 2017

One of the challenges of making quantitative estimates of failure likelihood on a new pipeline using industry incident statistics is that without careful selection and filtering of data, industry failure statistics are not directly applicable to modern pipeline designs, materials, and operating practices. As a result, industry failure statistics tend to over-state failure frequencies associated with new pipelines.

A review of industry failure statistics suggests that the majority of pipeline failures occur on pipelines that were installed in the 1970s or earlier (Mihell and Rout 2012). These pipelines were developed prior to the advent of several technologies that have enhanced pipeline reliability, such as:

- Continuous casting of steel slabs
- Thermomechanical controlled processing (TMCP) technology for skelp production (i.e., steel that is rolled or forged into narrow strips and ready to be made into pipe by being bent into a cylindrical shape and welded)
- HSLA steel design
- Low sulfur steels
- Inclusion shape control
- High toughness steels
- Implementation of quality systems and the use of highly constrained process control variables during pipe manufacture
- Highly-constrained mechanized welding processes using low-hydrogen welding processes
- Use of only non-destructive inspection methods
- High performance coating systems such as fusion bonded epoxy coatings
- Design-phase identification of internal corrosion threat factors and design of mitigation plans through internal corrosion modeling
- Identification of HVAC interference effects and development of mitigation plans through diagnostic testing of cathodic protection systems
- Implementation of quality management systems during design, construction and operations

Another challenge associated with the use of industry failure databases as the basis of a quantitative failure frequency assessment is that they do not address site-specific threats for a pipeline segment, such as geotechnical hazards.

Reliability methods have been widely adopted in the nuclear and aerospace industry, where they are used to identify and manage threats. In recent years, the pipeline industry has moved towards adopting this as a tool for risk studies. Pipeline industry research organizations such as the Pipeline Research Committee International (PRCI) and European Pipeline Research Group (EPRG) have developed reliability-based models for various threats. Reliability models employ limit state functions for the specific damage mechanism of interest in which the load variables and resistance variables are characterized in terms of probability density functions. This enables us to use reliability modeling techniques such as Monte Carlo Analysis to characterize the probability of incurring a failure on a pipeline. Reliability methods provide a powerful tool to make accurate, quantitative predictions on likelihood of failure over the expected lifespan of a pipeline.

Figure 4-8 illustrates how reliability methods can be utilized to quantify the probability of failure, based on a defendable approach.

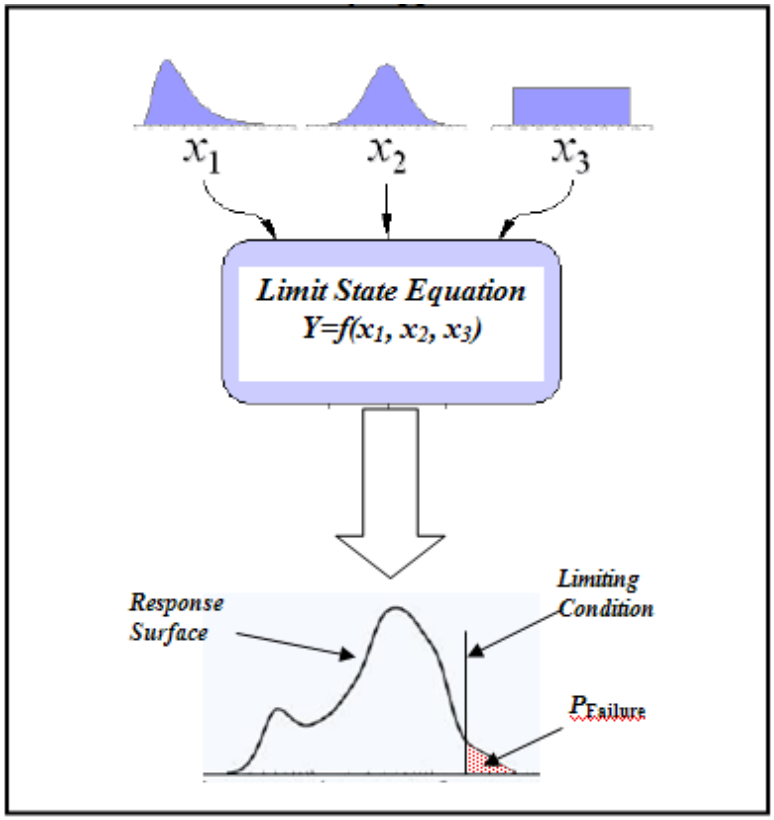

Figure 4-8 Reliability Approach

In the pipeline industry, reliability models exist for the most significant threats, including third party damage, internal corrosion and external corrosion.

The basis of every reliability model is a limit state equation that describes the failure conditions for the mechanism being considered. Furthermore, at least one of the input variables to this limit state equation must be characterized as a probability density function, as illustrated in Figure 4-8.

Therefore, a reliability approach is not possible for some threats, such as incorrect operations, where these probability density functions are not available. For these threats (which usually constitute second-order threats, in terms of failure likelihood magnitude), an alternative is to employ industry failure statistics, incorporating techniques such as the careful selection and filtering of incident data and/or means of accounting for differences in materials, design and operations that are characteristic of modern pipelines. For geotechnical threats, the likelihood of failure can be characterized in terms of expected magnitude and associated frequency of

occurrence, thereby enabling pipeline reliability to be established at each geotechnically-active site.

The approach used in estimating failure frequency for each threat is described in the remainder of this section.

4.2.3.2 External Corrosion

The reliability approach for external corrosion employs the application of an analogue ILI dataset, taking into account the design and materials for the L3RP (Mihell and Rout 2012).

As the wall thickness of the pipe segments vary between the seven modeling locations, a separate analysis was conducted for each wall thickness (in all cases, the pipe grade was X70) (Table 4-14). To provide a conservative assessment, the highest maximum operating pressure of any of the seven modeling locations for the L3RP was used in the analysis. The combinations of diameter, wall thickness, grade and maximum operating pressure that were used in the analysis are summarized in Table 4-14.

Table 4-14 Design Parameters Employed in Analysis

Diameter (in.)	Wall Thickness (in.)	MOP (psi)	Segments Represented
36	0.750	734.7	Sites 2,3,4,5,6,7
36	0.515	734.7	Site 1

4.2.3.2.1 Selection of Analogue ILI Data

Based on Mihell and Rout (2012), to estimate defect incidence rate, defect size distribution, and defect growth rate distribution, it is important that the analogue ILI dataset is representative of the degradation process and performance characteristics of the coating system to be used in with the L3RP.

After a review of candidate ILI datasets, the external wall loss feature list of interacted features (6t x 6t interaction rule) from the 2010 in-line inspection of Enbridge's Line 4 (BU-QU) was chosen.

As outlined in Mihell and Rout (2012), to reduce over-conservativism in the analysis, candidate ILI datasets were reviewed to remove wall loss data that cannot be attributed to active corrosion (e.g., benign manufacturing features). One effective method that can be used to screen for active wall loss is to use data derived from pit-matching for the same pipeline of separate in-line inspections. However, because pit-matched data was not available, and as described in Section 4.2.3.2.2, a conservative approach to determining corrosion growth rate was used.

Beyond the quality of ILI data, several other factors were considered in selecting the Line 4 dataset:

- Coating type (FBE in both Line 4 and in the proposed L3RP pipelines)
- Coating specification (i.e., the same Enbridge coating specification will apply to both Line 4 and the proposed L3RP pipelines)
- Operating environment (Western Plains are common to Line 4 and L3RP pipelines)
- Cathodic protection and other operating standards (i.e., the same Enbridge standards apply to Line 4 and L3RP pipelines)

Another important consideration was that the Line 4 data set represents fusion bond epoxy coated pipeline segments that were 11 years old at the time of inspection, having been installed in 1999, thereby enabling sufficient time for evidence of corrosion susceptibility to manifest itself on the ILI logs.

4.2.3.2.2 Reliability Approach

The reliability approach described in Mihell and Rout (2012) was used to estimate failure frequency as a function of pipeline age.

A Monte Carlo approach was developed to assimilate distributions derived from size and growth rate distributions derived from the analogue ILI dataset, and apply those distributions against the modified ASME B31G failure limit state criterion, which, for the purposes of the analysis, was rearranged to determine flaw depth at failure:

Equation 1

$$d_f = \mathrm{MIN}\left[(0.8t), \left(\frac{t\left(\sigma_{op} - \overline{\sigma}\right)}{0.85\left(\frac{\sigma_{op}}{M} - \overline{\sigma}\right)}\right)\right]$$

Where,

d_f = Depth at failure
t = Wall thickness
σ_{op} = Operating stress
$\overline{\sigma}$ = Flow stress
$M = \sqrt{1 + 0.6257\frac{L^2}{Dt} - 0.003375\left(\frac{L^2}{Dt}\right)^2}$
$(\text{for } L \le \sqrt{50Dt})$
$M = 3.3 + 0.032\frac{L^2}{Dt}$
$(\text{for } L > \sqrt{50Dt})$
L = Defect length

In the Monte Carlo analysis, the variables of pipe diameter, pipe wall thickness, yield strength, and operating pressure specific to each of the pipeline design combinations (Table 4-14) were used and a separate reliability analysis was completed for each combination of variables. Corrosion feature incidence rates and the distribution parameters for corrosion feature length and depth were determined from the analogue ILI data, as were corrosion feature growth rates.

When using ILI data for the purposes of establishing these parameters, it is important to recognize that the quantities derived represent values at a particular point in time (i.e., the date of last inspection). Furthermore, these quantities are subject to tool measurement error. Corrosion feature depth is therefore considered characteristic of the depth after some period of time. When applied to a new pipeline, the depth distribution must be adjusted downwards (accounting for some assumed corrosion growth rate) when the modeled pipeline age is less than that from which the analogue ILI data was obtained. Similarly, the depth distribution must be adjusted upwards when the modeled pipeline age is greater than that from which the analogue ILI data was obtained. This is illustrated in Figure 4-9, which shows how the flaw distribution flattens and translates with time (t). Specifically, as time increases, the mean of the flaw depth distribution and the standard deviation of the flaw depth distribution increase.

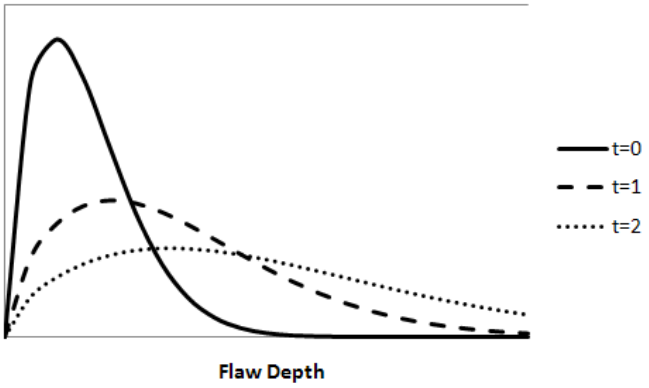

Figure 4-9 Illustration of How Flaw Depth Distribution Changes With Time

In the absence of any other information pertaining to how flaw depth growth rate varies with time, a linear growth rate assumption can generally be considered a reasonable, yet conservative approximation, since it ignores the polarizing effects of the accumulation of corrosion product.

The high-performance coating systems that are characteristic of modern pipelines, such as fusion bond epoxy are not susceptible to time-dependent coating degradation to the extent that older vintage coating systems are. Therefore, it was considered realistic to assume that any coating damage that is inferred from the presence of a corrosion feature was created at the

time of installation, and that the areal extent of coating damage, and hence the potential for increases in wall loss area (i.e., length and width) does not change appreciably with time.

In the Monte Carlo simulation, corrosion feature depth, as a function of time, and feature length are sampled stochastically, based on the probability density functions for those parameters derived from the analogue ILI dataset. A further stochastic adjustment on flaw depth is made to account for the tool error associated with the ILI tool from which the analogue data was derived. Because correlations derived from <Tool-Predicted> to <In-Ditch Measurement> data pairs were not available for the analogue dataset, a standard tool measurement error of ±10% wall thickness, 80% of the time was used. In statistical terms, this corresponds to a normal error distribution having a mean of 0, and a standard deviation of 7.8% of the wall thickness.

Assuming a linear flaw depth growth model, the stochastically-sampled flaw depth estimate was adjusted to account for the difference between the age of the analogue pipeline at the time that the ILI data was acquired, and the modeled age of the new pipeline:

Equation 2

$$\overset{o}{d}_A = \frac{\overset{o}{d} \cdot T_A}{T_{ILI}}$$

Where,

$\overset{0}{d}_A$ = Stochastically sampled flaw depth at the specific time assumed in the analysis

$\overset{0}{d}$ = Stochastically sampled flaw depth, derived from the analogue ILI dataset (incorporating stochastic adjustment for analogue ILI tool error)

T_A = Year of operation for the pipeline that is being assumed in the analysis

T_{ILI} = Year of operation for the analogue pipeline when the ILI assessment was completed.

For the purposes of the Monte Carlo simulation, all pipe parameters that are contained in the limit state function shown in Equation 1 (i.e., pipe wall thickness, operating stress level, and flow stress) correspond to each of combination of pipeline design variables reported in Table 4-14.

Failure is predicted when the stochastically sampled flaw depth derived from Equation 2 exceeds the flaw depth that defines the limiting condition (derived from Equation 1). When the Monte Carlo simulation is performed through multiple iterations, the probability of failure for the given year of analysis is defined as the proportion of those iterations that return a failure prediction. This probability is defined as the probability of failure, given the presence of a corrosion feature, $P_{f,F}$. The overall probability of failure for a given pipeline segment in the year of operation being considered in the analysis is defined as:

Equation 3

$$P_{f,DS} = \rho_{ILI} \cdot \frac{D_N}{D_{ILI}} \cdot L_{DS} \cdot P_{f,F}$$

Where:

$P_{f,DS}$ = Probability of failure for the pipeline segment
ρ_{ILI} = Corrosion feature density per unit length of pipeline derived from the analogue ILI dataset
D_N = Diameter of the pipeline
D_{ILI} = Diameter of the pipeline from which the analogue ILI data was derived
L_{DS} = Length of the pipeline segment
$P_{f,F}$ = Probability of failure, given the presence of a corrosion feature.

4.2.3.2.3 Determination of Leak and Rupture

To support a risk analysis, the output from the failure frequency analysis must be relevant to the fates and effects analysis (Chapters 6.0 and 7.0). Therefore, the results of a failure frequency analysis must specify more than frequency of occurrence; instead, the frequencies of occurrence must be tied to an outcome, with the outcome being the volume of the crude oil release. As discussed in Chapter 3.0, a release volume corresponding to a most-credible worst-case scenario, involving a rupture was determined for each of the seven modeling locations.

In the reliability analysis for external corrosion failure likelihood, the proportion of ruptures are determined by first calculating the critical through-wall flaw size as a function of material properties and operating parameters of the pipeline segment. The NG-18 flaw equation was used to determine the critical through-wall flaw size (Eiber and Leis 2001):

Equation 4

$$K_c^2 = \frac{12 \cdot C_v \cdot E}{A_c} = \frac{8 \cdot c \cdot \overline{\sigma}^2}{\pi} \ln \sec\left[\frac{\pi \cdot M_T \cdot \sigma_h}{2 \cdot \overline{\sigma}}\right]$$

The above relationship is commonly used to determine the maximum size defect that will leak rather than rupture. At high fracture toughness values, it represents a flow-stress or plastic instability criterion (typical of the failure mode of most corrosion features), whereas at lower fracture toughness values, it may represent a conservative representation of the leak/rupture boundary for corrosion features.

As illustrated in Figure 4-10, the cumulative distribution function for flaw length, derived from the analogue ILI dataset was compared against the critical through-wall flaw length for each set of pipeline design variables modeled. Using this approach, the proportion of features that have the

potential to penetrate through-wall at a length greater than the critical through-wall flaw length can conservatively be said to have the potential to fail in rupture mode, while the remainder of the flaws will fail as leaks.

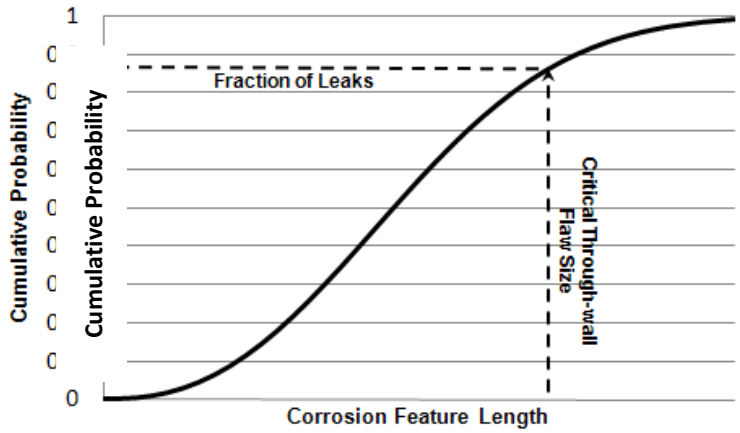

Figure 4-10 Determination of Fraction of Leaks and Ruptures from Corrosion Feature Length CDF and Critical Through-Wall Flaw Size

Because critical through-wall flaw length is a function of wall thickness and operating pressure, the proportion of leaks was determined for each combination of pipeline design variables modeled, based on the feature length distribution obtained from the analogue ILI dataset.

4.2.3.2.4 Results—Unmitigated Analysis

By performing a separate analysis for each year of operation, and for each dynamic segment, an external corrosion reliability plot was generated for each year of operation for each wall thickness for the L3RP for the 7 modeling locations out to 20 years after installation. It is important to note that in the unmitigated analysis, each corrosion feature is allowed to grow throughout the full time period covered for the analysis. This represents a significantly conservative assumption, as in reality, several measures will be employed to mitigate corrosion, including:

- Regular cathodic protection surveys will be conducted, and any lows will be immediately remediated
- ILIs will be completed on a regular basis, and any features that exceed the acceptance criteria established in CFR 49 Part 195 will be excavated, examined, and repaired or re-coated
- In practice, even when left unmitigated, corrosion growth rates tend to decline with the passage of time due to the accumulation of corrosion products. This natural tendency for decreasing corrosion growth rates with time has been disregarded in the analysis.

Two sets of analyses were performed; one for 36-inch diameter, 0.515-inch wall thickness (Site 1), and one for 36-inch diameter, 0.750-inch wall thickness (Sites 2,3,4,5,6,7).

The reliability plot for the 0.515-inch wall thickness case is presented in Figure 4-11. As can be seen from this plot, the estimated rupture frequency is essentially zero (less than 10^{-40}) for at least the first 20 years of operation. No reliability plot has been provided for the 36-inch diameter, 0.750-inch wall thickness case, as finite (non-zero) values were not obtained through the 20 year analysis period. This reflects a lack of failure sensitivity of both of the L3RP design cases to the expected probability distributions that characterize corrosion feature initiation and growth over that 20 year period.

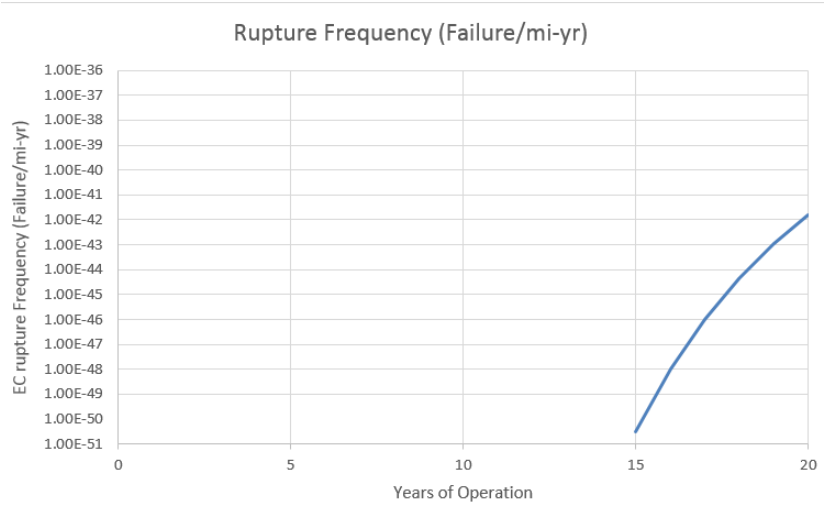

Figure 4-11 External Corrosion Reliability Plot: 36" L3RP 0.515" WT

4.2.3.2.5 Results—Consideration of Operations and Maintenance

The analysis of unmitigated external corrosion failure likelihood demonstrates the relative lack of sensitivity of external corrosion rupture frequency over time, relative to the planned five-year ILI reassessment interval. Specifically, the rupture frequency attributed to the threat of external corrosion is essentially zero for the first 20 years of operation for each of the L3RP design cases evaluated. This 20-year period reflects a time period during which 5 ILIs (including a baseline inspection) for wall loss are planned to occur. Given this lack of time-sensitivity to failure, relative to the planned ILI interval, it is reasonable to expect that any external corrosion features that may initiate will be detected and monitored for pre-emptive repair so that they can be mitigated before they can reach a critical size for failure. Given this circumstance, it is not possible to arrive at a finite value of expected failure frequency over the long term. Nevertheless, a failure frequency value of 10^{-08} ruptures/mi.yr (which the analysis shows to be conservative) will be assigned to this threat, and will be applied to all seven modeling locations.

4.2.3.3 Internal Corrosion

The reliability approach for internal corrosion is consistent with the approach described for external corrosion. However, in regard to the selection of candidate analogue ILI data, the considerations required to evaluate and compare the corrosion conditions for the L3RP with those of the candidate analogue datasets are different than those employed for an assessment of external corrosion.

4.2.3.3.1 Selection of Analogue ILI Data

One of the simplest methods to perform screening for internal corrosion is to view orientation charts for internal wall loss features. Where water drop-out and accumulation is an essential aspect of the internal corrosion mechanism that is associated with the product and flow characteristics being considered (as is the case here), wall loss that is associated with internal corrosion should be expected at the bottom of the pipe, as illustrated in Figure 4-12.

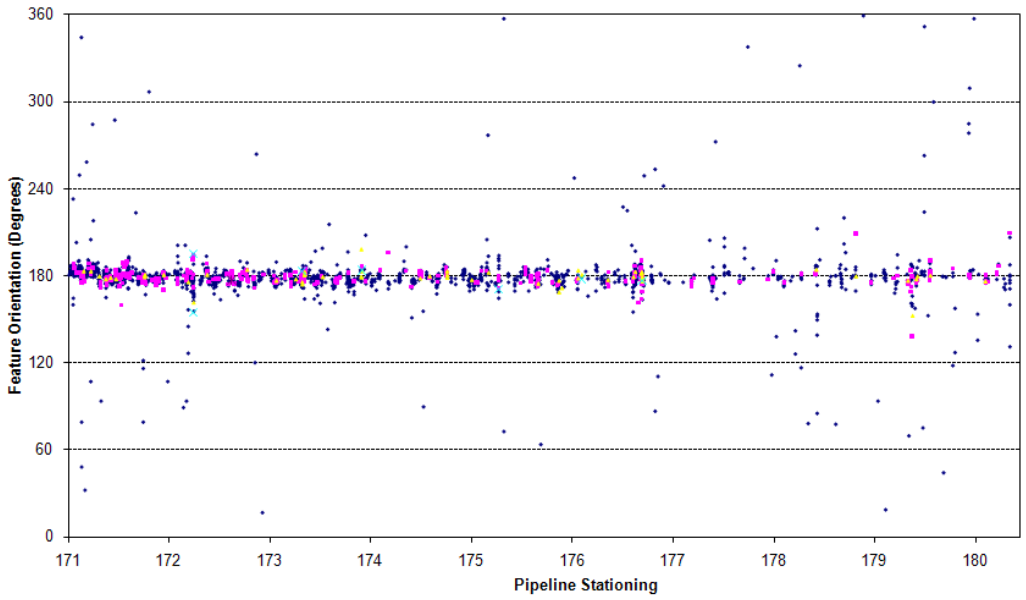

Figure 4-12 Six O'Clock Orientation Typical of Water Drop-out and Accumulation

On the other hand, a random distribution of internal wall loss features around the circumference of the pipe, with no apparent trends relative to inclination angle or receipt points might be more representative of benign manufacturing imperfections, as is represented in Figure 4-13.

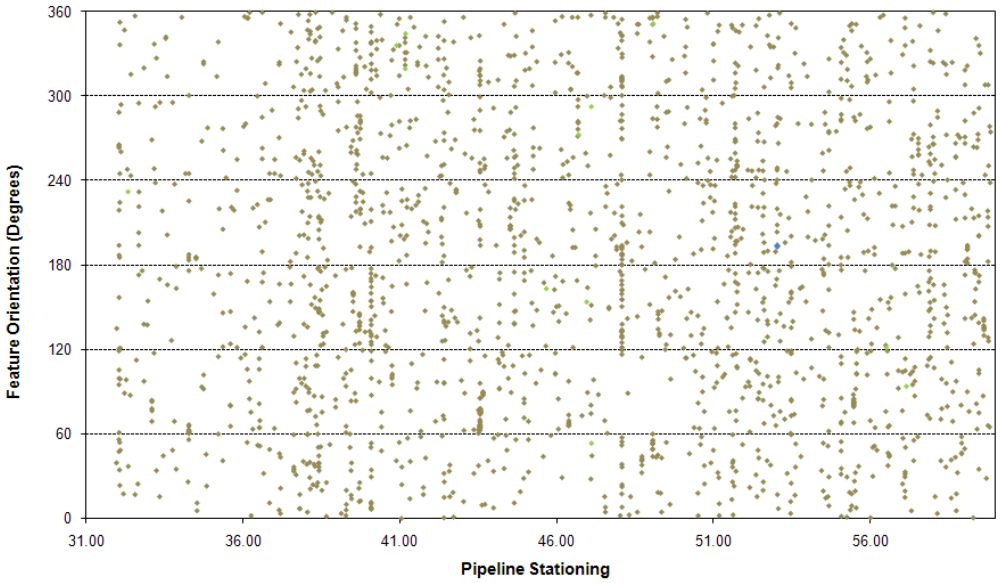

Figure 4-13 Random Wall Loss Orientation Typical of Manufacturing Imperfections—No Apparent Active Internal Corrosion

Internal corrosion evaluation techniques are largely based on product stream characteristics and flow rates. For liquid products, the important parameters that should be included in a comparison of corrosivity are water content, erosion and erosion/corrosion, flow velocity, flow mechanism, temperature, susceptibility to under-deposit corrosion (solid deposition, MIC potential, and water chemistry), and mitigation measures (use of inhibition, biocides, or pigging).

To ensure that the corrosion mechanism and corrosivity that is represented by the analogue ILI dataset is representative of that which would be expected in the L3RP, an evaluation of all of these parameters was conducted. Through this process, it was determined that ILI data obtained from Enbridge's 36-in. Line 4 would be most representative of the corrosivity conditions expected on the L3RP, since Line 4 transports similar products with similar tariffs in similar hydraulic regimes. A review of historical operating conditions on Line 4 indicates that like the proposed L3RP, the product flows in a fully-turbulent regime. Line 4 has historically transported both conventional and heavy crude oil and dilbit, with a tariff of 0.5% basic sediment and water (BS&W), which is the same tariff assigned to the L3RP.

4.2.3.3.1.1 Line 4 ILI Data

Approximately 10,000 km/year of ILI data from the 36-inch Line 4 was reviewed (i.e., approximately 1,000 km of 36-inch Line 4, having an average age of approximately 10 years at the time of inspection), with no evidence of active internal corrosion. The fully-turbulent mode of flow that is characteristic of 36-inch Line 4 and that will also be characteristic of the L3RP results in full entrainment of what little water is present at a BS&W content of less than 0.5%.

In such circumstances, water cannot stratify or accumulate adjacent to the pipe wall, and the internal surface of the pipeline remains in an oil-wet condition. This condition is not associated with internal corrosion.

Regular assessments for corrosion on the L3RP will be completed at no more than 5-year intervals. Given the demonstrated lack of failure-sensitivity to the initiation and growth of internal corrosion over a time period that is approximately double the inspection interval, it was concluded that it is not possible to arrive at a finite value of expected failure frequency for this threat. Nevertheless, a failure frequency value of 10-08 ruptures/mile/year (which the analysis shows to be conservative) will be assigned to this threat, and will be applied to all seven modeling locations.

4.2.3.4 Third Party Damage

The approach used for determining the reliability of a pipeline from the perspective of third party damage was based on the approach developed by Chen and Nessim (1999a). In this approach, failure frequency can be established as the product of two independent variables; the frequency of incurring a hit by an excavator, and the probability of failure given such a hit:

Equation 5

$$FF_{3PD} = F_H \cdot P_{F,H}$$

Where,

FF_{3PD} = Failure frequency due to third party damage
F_H = Excavator hit frequency (hits/km.yr)
$P_{F,H}$ = Probability of failure, given a hit

Chen and Nessim (1999b) demonstrated that machines smaller than excavators do not significantly affect predicted failure probability. Based on this finding, only impacts by large machines such as excavators are addressed by this model.

4.2.3.4.1 Determination of Impact Frequency Due to Third Party Activity

The impact frequency due to third party activity was determined by using a fault tree model developed by Chen and Nessim (1999b). This fault tree model is illustrated in Figure 4-14 and Table 4-15.

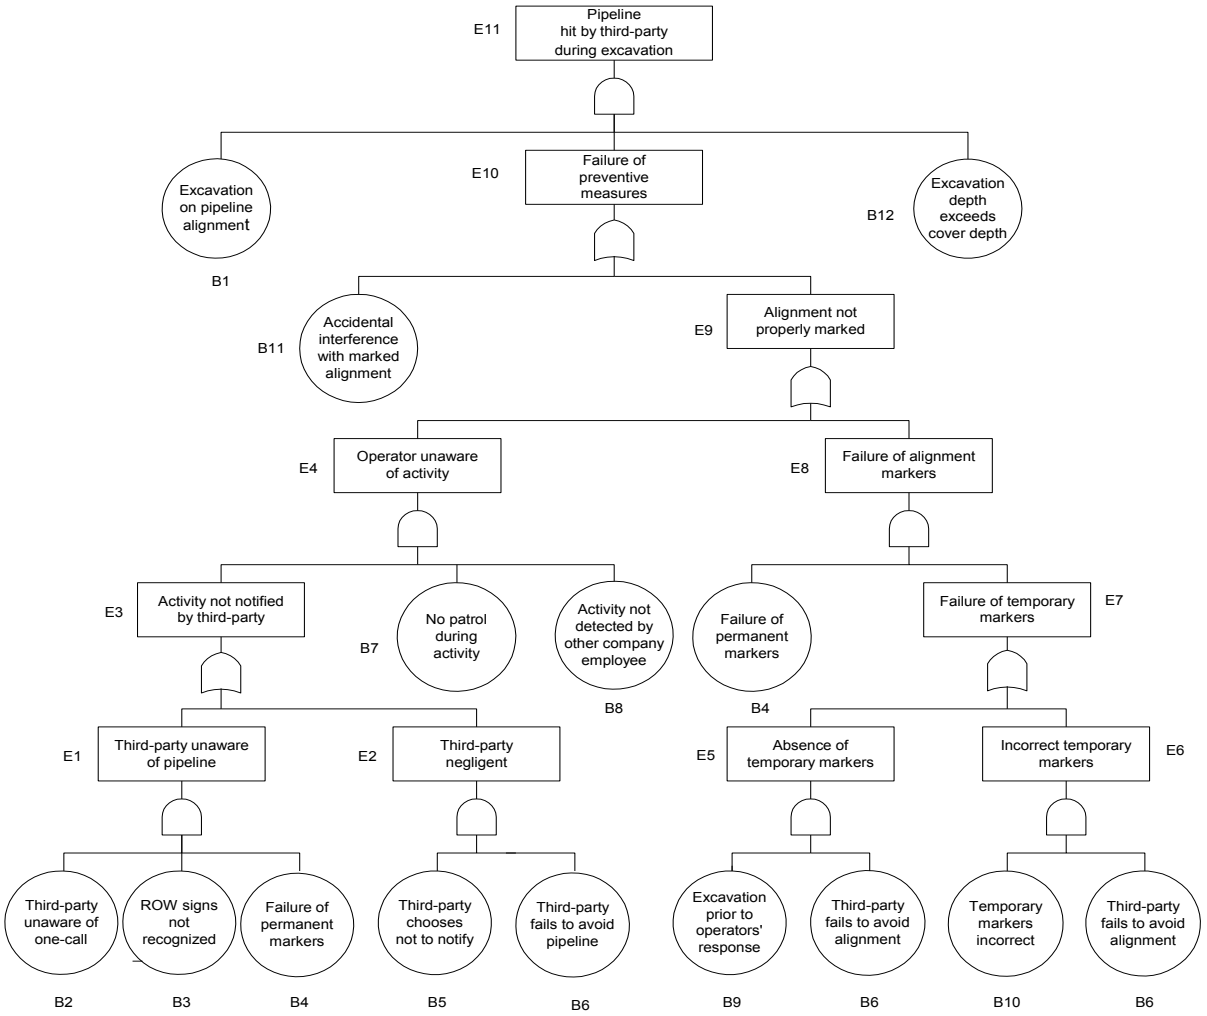

Figure 4-14 Impact Frequency Fault Tree

Table 4-15 Probability Values for Fault Tree Modeling

No	Event	Conditions	Probability
B1	Excavation on pipeline alignment	Commercials/Industrial	0.52/km-year
		High density residential	0.26/km-year
		Low density residential	0.36/km-year
		Agricultural	0.076/km-year
		Remote	0.06/km-year
B2	Third-party unaware of one-call	Advertising via direct mail-outs and promotion among contractors	0.24
		A1+Community meetings	0.10
		Community meetings only	0.50
B3	Right-of-way signs not recognized	Signs at selected crossings	0.23
		Signs at all crossings	0.19
		All crossings plus intermittently along route	0.17
B4	Failure of permanent markers	No buried markers	1.00
		With buried markers	0.10
B5	Third-party chooses not to notify	Voluntary	0.58
		Mandatory	0.33
		Mandatory plus civil penalty	0.14
		Right-of-way agreement	0.11
B6	Third-party fails to avoid pipeline	N/A	0.40
B7	ROW patrols fail to detect activity	Semi-daily patrols	0.13
		Daily patrols	0.30
		Bi-daily patrols	0.52
		Weekly patrols	0.80
		Biweekly patrols	0.90
		Monthly patrols	0.95
		Semi-annual patrols	0.99
		Annual patrols	0.996
B8	Activity not detected by other employees	N/A	0.97
B9	Excavation prior to operator's response	Response at the same day	0.02
		Response within two days	0.11
		Response within three days	0.20

Table 4-15 Probability Values for Fault Tree Modeling

No	Event	Conditions	Probability
B10	Temporary mark incorrect	By company records	0.20
		By magnetic techniques	0.09
		By pipe locators/probe bars	0.01
B11	Accidental interference with marked alignment	Provide route information	0.35
		Locate/mark	0.17
		Locate/mark/site supervision	0.03
		Pipe exposed by hand	0.06
B12	Excavation depth exceeding cover depth	Cover depth = 0.8 m (2.5 ft)	0.42
		0.9 m (3 ft)	0.25
		1.2 m (4 ft)	0.08
		1.5 m (5 ft)	0.07
		1.8 m (6 ft)	0.06

The fault tree model was used in conjunction with design, installation and operations data for the L3RP that was supplied during the Threat Assessment Workshop.

4.2.3.4.2 Determination of Failure Probability, Given Excavator Impact

Given a failure in the measures to prevent the accidental contact of an excavator with the pipeline, a loss of containment may occur due to gouge-in-dent or puncture mechanisms, or alternatively a failure may not occur. The frequency of having a gouge-in-dent or puncture failure, given a contact with an excavator, is a function of whether or not the pipeline resistance (a function of grade, wall thickness, and toughness) is greater or less than the driving forces for failure (a function of excavator force, bucket tooth dimensions, operating pressure). Where the resistance of the pipeline to failure exceeds the driving forces, no failure will occur. Otherwise, failure will occur.

Where failures occur that are related to external interference, the mode of failure is more likely to be gouge-in-dent than puncture (Fuglem et al. 2001; Eiber and Leis 2001). This is in part due to the fact that less force is required to cause a gouge-in-dent failure than is required to puncture a pipeline.

The model that determines the probability of failure, given a hit was derived based on the work reported in Fuglem et al. (2001), utilizes a Monte Carlo analysis to assimilate the probability distributions of the various parameters employed. An overview of the approach is provided below.

4.2.3.4.2.1 Test for Gouge-in-Dent

Gouge-in-dent failure has been empirically described by the NG-18 Q-Factor Relationship (Eiber and Leis 2001).

Equation 6

$$\sigma_h = \sigma_{fl}\left[\frac{(Q - C_2)^{0.6}}{C_3}\right]$$

Where,

- σ_h = Hoop stress at failure (ksi or MPa)
- σ_{fl} = Flow stress (ksi or MPa)
  = Y.S. + 10 ksi or Y.S. + 68.9 MPa
- C_2 = a constant
  = 300 ft-lbs/in or 16 J/mm
- C_3 = a constant
  = 90 (ft-lbs/in)0.6 or 4.80 (J/mm)0.6

Equation 7

$$Q = c_{v,2/3}\left[\frac{R\,t}{D\,d_g\,c_g}\right]$$

Where,

- $C_{v,2/3}$ = 2/3 upper-shelf charpy toughness (ft-lbs or J)
- R = Pipe radius (in. or mm)
- t = Wall thickness (in. or mm)
- D = Maximum dent depth at the time of defect introduction (in. or mm)
- d_g = Depth of gouge (in. or mm)
- c_g = ½ gouge length (in. or mm)

The input parameters utilized in the analysis are described below.

4.2.3.4.2.2 Flow Stress (σfl)

As defined above, flow stress is a function of yield strength. Yield strength distribution parameters were obtained from Fuglem et al. (2001), which indicates that yield strength is normally distributed, with distribution parameters as follows:

- μ = 1.1(SMYS)
- COV = 0.035(SMYS)

4.2.3.4.2.3 Charpy Toughness (cv)

The toughness for the L3RP was conservatively estimated at 40J (29.5 ft-lb), full-size, which corresponds to the minimum specified value for pipe that will be ordered for this pipeline. This is considered quite conservative, since modern pipeline materials easily exceed this value.

4.2.3.4.2.4 Pipe Radius (R)

Pipe radius is a function of pipe diameter (D). Pipe diameter distribution parameters were obtained from Fuglem et al. (2001), which indicates that pipe diameter is normally distributed, with distribution parameters as follows:

μ = 1.0 (nominal diameter)
COV = 0.0006 (nominal diameter)

4.2.3.4.2.5 Wall Thickness (t)

Wall thickness distribution parameters were obtained from Fuglem et al. (2001), which indicates that wall thickness is normally distributed, with distribution parameters as follows:

μ = 1.0 (nominal wall thickness)
COV = 0.01 (nominal wall thickness)

4.2.3.4.2.6 Ultimate Tensile Strength (UTS)

Ultimate tensile strength distribution parameters were obtained from Fuglem et al. (2001) which indicates that ultimate tensile strength is normally distributed, with average and standard deviation values on API 5L X70 pipe of 639.2 MPa (92.7 ksi) and 22.4 MPa (3.2 ksi), respectively.

4.2.3.4.2.7 Excavator Force (Fd)

Maximum Excavator Force Capacity (Fd, kN) has been shown to be a function of excavator mass (mex, tonnes) (Roovers et al. 2000).

Equation 8

$$F_d = 14.2 \cdot m_{ex}^{0.928}$$

Driver and Zimmerman (1998) presented a distribution of excavators by machine mass. This is the same excavator mass distribution that was employed in Fuglem et al. (2001); specifically the entire excavator mass distribution may be applied for Class 1 and Class 2 locations, while a sub-set of that distribution (i.e., excluding excavator masses in excess of 40 tonnes) is applicable to Class 3 and 4 locations. By performing cumulative probability transformations of the excavator mass distributions, and applying Equation 8, sixth-order polynomial curve fits can be made to the data for both the Class 1/2 and Class 3/4 datasets, as illustrated in Figure 4-15 and Figure 4-16. These regression functions were incorporated directly in the Monte Carlo simulations.

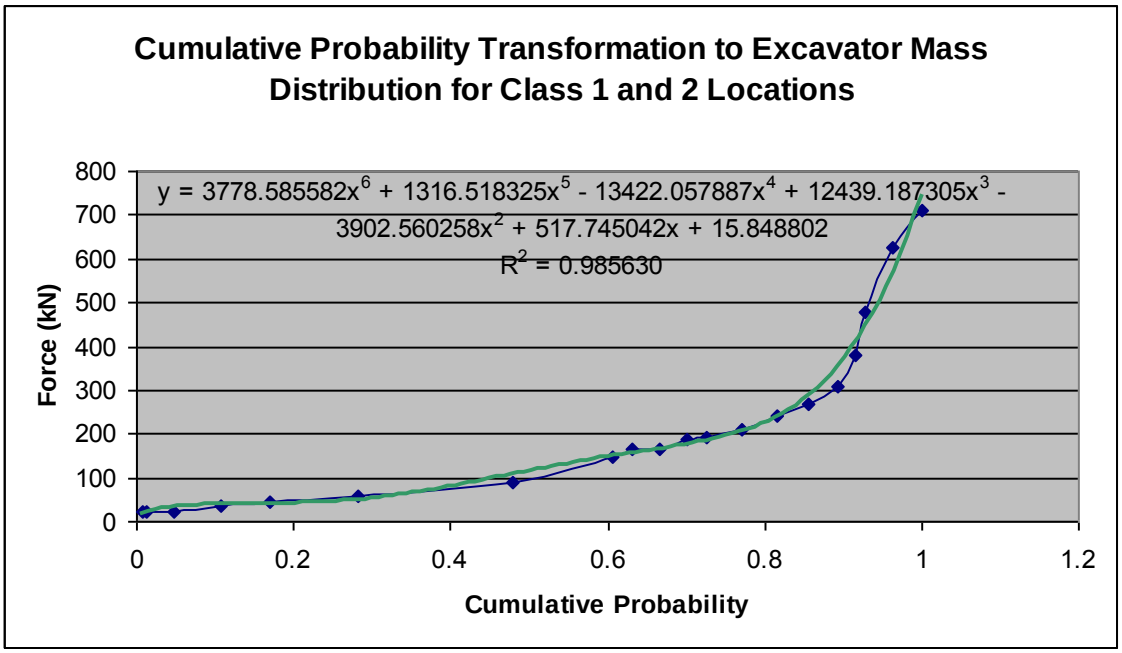

Figure 4-15 Excavator Mass Distribution, Class 1 and 2 Locations

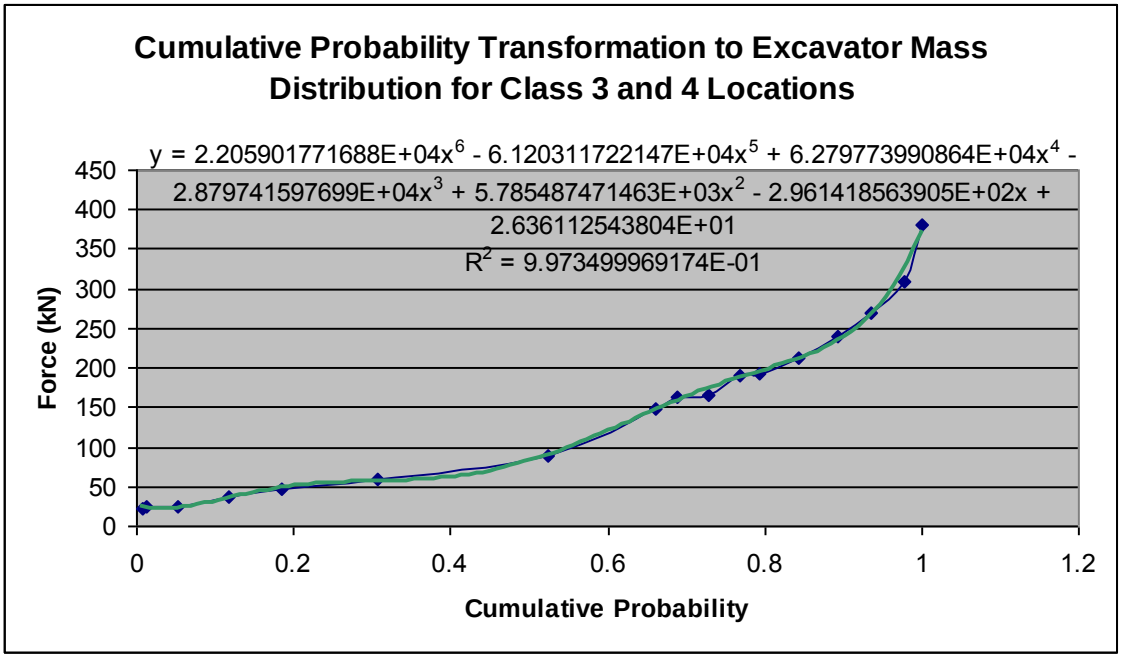

Figure 4-16 Excavator Mass Distribution, Class 3 and 4 Locations

4.2.3.4.2.8 Excavator Tooth Dimensions: Length (L) and Width (W)

The excavator bucket tooth size parameters tooth length (L, mm) and tooth width (W, mm) have been shown to be a function of excavator mass (mex, tonnes) (Roovers et al. 2000).

Equation 9

$$(L + W) = 29.4 \cdot m_{ex}^{0.400}$$

Equation 10

$$L = 24.6 \cdot m_{ex}^{0.420}$$

These parameters were therefore derived as functions of the excavator mass distribution.

4.2.3.4.2.9 Dent Depth (H)

Dent depth has been shown to be a function of pipe diameter, ultimate tensile strength, excavator tooth Length, wall thickness, operating pressure (Pop) and excavator force (Roovers at al. 2000).

Equation 11

$$P_r = \sqrt{t^3 \cdot UTS \cdot L}\left[1 + 0.7\left(\frac{P_{op} \cdot D}{t \cdot UTS}\right)\right]$$

Where,

- UTS = Ultimate Tensile Strength (MPa),
- L = Tooth Length (mm),
- P_{op} = Maximum Operating Pressure (MPa),
- D = Pipe Diameter (mm),
- t = Pipe Wall Thickness (mm),
- P_r = Pipeline Resistance Parameter (mm(N)0.5), where:

Equation 12

$$\text{If } P_r \le 2000\,mm \cdot \sqrt{N} : H = \left(\frac{F_d}{0.007 \cdot P_r}\right)^2$$

Equation 13

$$\text{If } P_r > 2000\ \text{mm}\cdot\sqrt{N} : H = \left(\frac{F_d}{0.31\cdot\sqrt{P_r}} \right)^2$$

Where,

F_d = Denting Force (kN),
H = Dent depth, measured after damage under pressure (i.e., after re-rounding under pressure) (mm).

A relationship exists between H and Ho (the dent depth prior to re-rounding under pressure) (Roovers et al. 2000):

Equation 14

$$H_o = 1.43 \cdot H$$

4.2.3.4.2.10 Gouge Depth (dg)

In Fuglem et al. (2001), reference was made to a judgment-based decision to assume that the gouge depth distribution could be defined as a random variable described by a Weibull distribution having μ = 0.5 mm and σ = 0.5 mm. Conversations with researchers who were involved in full-scale experimental testing of third party damage revealed an unpublished dataset showing that gouge depth is a function of excavator force. A straight-line regression was found to fit this dataset having the form:

Equation 15

$$\text{Gouge Depth (in)} = 3.268 \times 10^{-4} \cdot F_d\text{(kN)} - 5.851 \times 10^{-3}$$

It should be noted that the 50th percentile force from Figure 4-17 is approximately 100 kN. If this value is substituted into Equation 15, a gouge depth of 0.027" is obtained, which corresponds very closely to the mean value of 0.5 mm that is cited in Fuglem et al. (2001).

Accordingly, it was decided to correlate the gouge depth distribution to the excavator force distribution by means of Equation 15.

4.2.3.4.2.11 Half Gouge Length (cg)

Fuglem et al. (2001) and Eiber and Leis (2001) were referenced to establish a basis for a gouge length distribution. It was determined that unlike gouge depth, gouge length is independent of other variables such as excavator force. In Fuglem et al. (2001), the gouge length distribution was described using a Weibull distribution having a mean of 6.0 in., and a COV of 1.25. Gouge length was described as having an approximate value of 3 in., and an upper-bound value of 25 in. (Eiber and Leis 2001). It was noted that the dataset compiled in Eiber and Leis (2001) was

derived from mechanical damage defects that failed in-service, and so the upper-bound gouge length may be taken as a statistical outlier. On the basis of this review, it was decided to describe the gouge length distribution as a Weibull distribution, having the shape parameters a = 1.2 and β = 3.2. This distribution is illustrated in Figure 4-17.

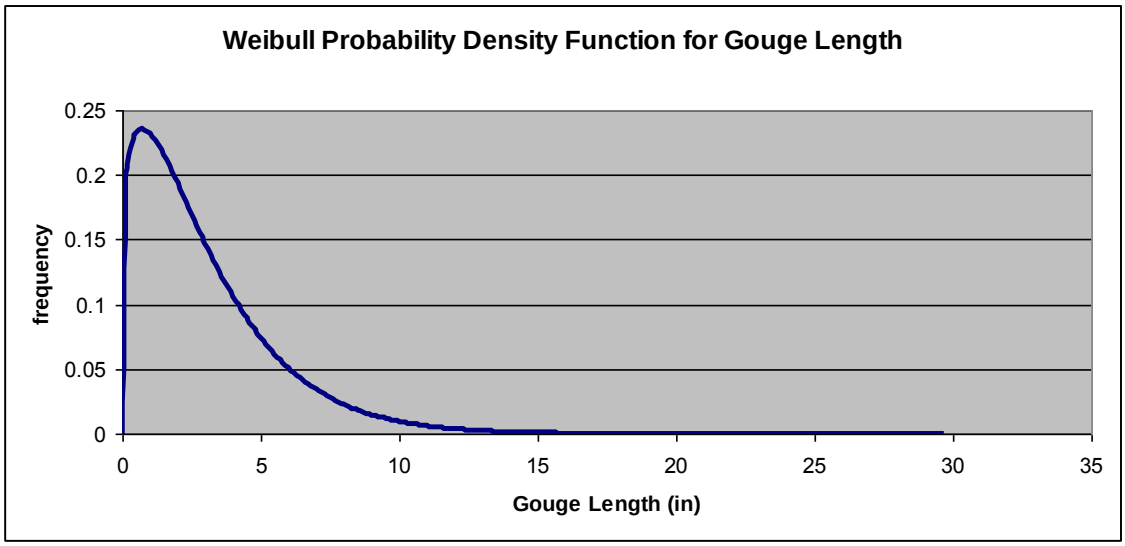

Figure 4-17 Gouge Length Distribution

Because gouges may be randomly oriented with respect to the axis of the pipe, a gouge orientation factor is applied against the gouge length. This is derived by recognizing the fact that the projected length of a gouge on the pipe axis is proportional to the cosine of the angle between the gouge and the pipe axis. The gouge length orientation factor; therefore, varies between 0 and 1 and is equal to the cosine of a uniform distribution of random angles between 0 and π/2 radians. A cumulative probability transformation on this distribution was performed, and a second order polynomial curve fit was derived for this function, as depicted in Figure 4-18.

This polynomial function was incorporated directly within the Monte Carlo simulation.

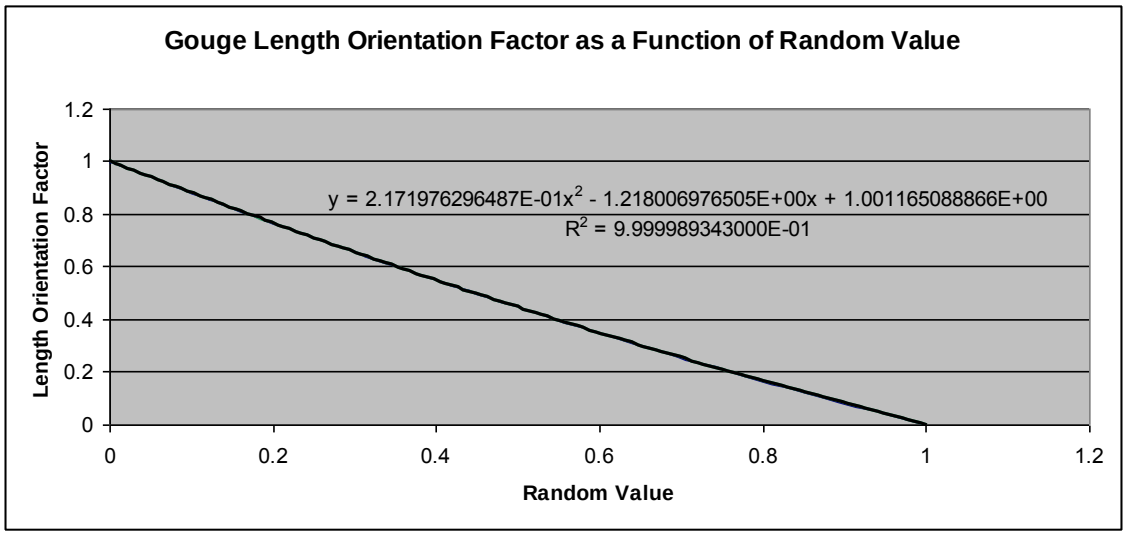

Figure 4-18 Gouge Length Orientation Factor

4.2.3.4.2.12 Off-Angle Force Reduction Factor

When the excavator force is applied normal to the pipeline, the full penetrating force of the excavation equipment can be brought to bear against the pipeline. When the applied force is at an angle θ to the pipe, the component of the maximum applied force that is directed towards penetration of the pipeline is equal to FMax Cos θ, as illustrated in Figure 4-19.

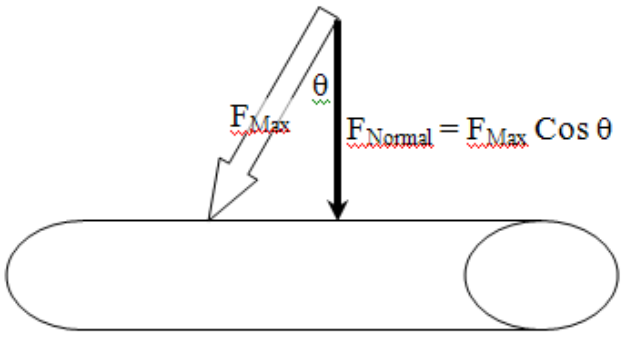

Figure 4-19 Off-Angle Force Reduction Factor

As presented by Fuglem et al. (2001), since the angle of the application of excavator force may be equally likely to be any angle between 0 and 90°, the off-angle force reduction factor is best described as a uniform distribution between 0 and 1.

4.2.3.4.2.13 Operator Control Factor

As discussed in Fuglem et al. (2001), the operator of a piece of excavation equipment will, in most cases, apply a load that is considerably less than the maximum quasi-static load. The typical actual capacity at which the machine is used will depend on the soil type and how aggressively the operator digs. It may also be expected that an operator may dramatically cut back on the load if he detects a foreign object. This may be particularly true for gouge-in-dent type damage, which is inflicted more gradually than puncture damage. Because of the uncertainty regarding the distribution of applied force, the approach by Fuglem et al. (2001) was used to calibrate the model against "Probability of Failure, Given a Hit" data for the operator control factor.

4.2.3.4.2.14 Test of Failure Due to Puncture

Puncture failure has been empirically described by the model described by Chen and Nessim (1999b).

Equation 16

$$R = \left[1.17 - 0.0029 \cdot \left(\frac{D}{t}\right)\right] \cdot (L + W) \cdot t \cdot \sigma_u + E_R$$

Where:

- R = The resistance to puncture (N)
- D = Pipe diameter (mm)
- t = Wall thickness (mm)
- L = Excavator tooth length (mm)
- W = Excavator tooth width (mm)
- σ_U = Ultimate tensile strength (MPa)
- E_R = Model error (N)

This is the same limit state equation used to define puncture resistance in Fuglem et al. (2001).

4.2.3.4.2.15 Input Parameters

With the exception of the operator control factor, all of the input parameters that are required for the puncture model have been defined in the discussion on the gouge-in-dent model. To avoid repetition, only the operator control factor will be described in this section.

As was done for the gouge-in-dent model, due to the lack of certainty regarding the distribution that describes the degree of operator control, the puncture model was calibrated against "Probability of Failure, Given a Hit" data contained in Fuglem et al. (2001).

4.2.3.4.2.16 Monte Carlo Simulation

Monte Carlo simulation is a numerical approach for arriving at a solution when the variables within a mathematical expression are best described as random variables derived from probability density functions, rather than discrete values, as is the case with a conventional

deterministic analysis. When used as part of a reliability analysis, the mathematical expression is known as a "limit state equation", and the usual objective of the analysis is to estimate the probability of an event or "limiting condition" occurring.

The limiting condition is usually one which describes the onset of failure, or some other undesirable event. In the case at hand, two limit state equations are used; one to define the onset of gouge-in-dent failure (Equation 6) and the other to define the onset of failure due to puncture (Equation 16).

The probability of failure given a hit due to gouge-in-dent is obtained by employing a Monte Carlo Simulation to determine the frequency of occurrence (over a set number of iterations) of events where the operating hoop stress due to internal pressure (σh) exceeds the operating stress at failure, as defined in Equation 6. Similarly, the probability of failure given a hit due to puncture is obtained by employing a Monte Carlo Simulation to determine the frequency of occurrence (over a set number of iterations) of events where the factored excavator force exceeds the resistance, R, as defined in Equation 16.

The overall probability of failure given a hit is determined by executing the Monte Carlo Simulations for gouge-in-dent and puncture simultaneously, and determining the frequency of occurrence (over a set number of iterations) of events where either the limit state for gouge-in-dent or puncture is exceeded.

4.2.3.4.3 Calibration

Calibration of this model was undertaken as described in the Sections describing the operator control factor for each of the two limit states. This approach is consistent with what was carried out in Fuglem et al. (2001), and it was achieved utilizing the calibration data from that study.

4.2.3.4.4 Leaks and Ruptures

It has been reported that the respective percentages of leak and rupture for third party damage failures are 75% and 25%, based on the mechanical damage incidents reported to the U.S. Department of Transportation during 1984 to 1992 (Chen and Nessim 1999b). Accordingly, third party damage failure rates established by the reliability approach described above are sub-divided into leaks and failures in accordance with this guideline.

4.2.3.4.5 Results

The length-averaged third party damage rupture frequency values for each of the seven modeling locations are summarized in Table 4-16.

Table 4-16 Third Party Damage Summary

Site	Third Party Damage Rupture Frequency (Ruptures/mi.yr)
1—Mosquito Creek	1.026×10^{-06}
2—Mississippi River at Ball Club	6.680×10^{-08}
3—Sandy River	6.680×10^{-08}
4—Shell River	6.680×10^{-08}
5—Red River	8.183×10^{-08}
6—Mississippi River at Palisades	6.680×10^{-08}
7—Mississippi River at Little Falls	1.733×10^{-07}

4.2.3.5 Manufacturing Defects

Manufacturing Defects failures are those that are attributed to pipe as a direct result of the presence of pipe body or seam weld defects.

The threat of manufacturing defects does not lend itself to failure frequency estimation using a reliability approach due to the lack of a limit state model that is supported by probability distributions for its input parameters. Therefore, the approach that was used to estimate the frequency of occurrence for this threat applies a failure frequency derived from industry failure statistics for modern (1980 installation or later) pipeline materials, design, and installation practices.

4.2.3.5.1 Failure Frequency for Manufacturing Defects

4.2.3.5.1.1 Analysis if Incident Data

The PHMSA Hazardous Liquids incident database (2010–present, current to December 31, 2015) was filtered for onshore, pipelines installed since 1980. For the purposes of isolating only those incidents associated with pipelines (i.e., not including facilities), the PHMSA incident database was filtered so that it included only those incidents that were related to "Onshore Pipelines, Including Valve Sites".

For the purposes of the "Pipelines Only" analysis, failures related to non-pipe equipment were not considered, thereby providing a suitable basis for estimating failure rates associated with pipeline ROWs.

To highlight failures characterized as "ruptures", a filter was applied to the "Release Type" field of the PHMSA flagged hazardous liquids incident database. The *Instructions for Form PHMSA F700-1 Accident Report—Hazardous Liquid Pipeline Systems* defines the term "leak" as follows: "Leak means a failure resulting in an unintentional release of the transported commodity that is often small in size, usually resulting in a low flow release of low volume, although large volume leaks can and do occur on occasion."

Conversely, the term "rupture" is defined as follows: "Rupture means the pipeline facility has burst, split, or broken and the operation of the pipeline facility is immediately impaired. Pipeline ruptures often result in a higher flow release of larger volume. The terms "circumferential" and "longitudinal" refer to the general direction or orientation of the rupture relative the pipe's axis. They do not exclusively refer to a failure involving a circumferential weld such as a girth weld, or to a failure involving a longitudinal weld such as a pipe seam."

For the purposes of categorization, failures that were characterized as "Mechanical Puncture" were included within the "Rupture" category.

Once the above filters were applied, the number of ruptures that were associated with materials defects over the reporting period was counted.

4.2.3.5.1.2 Analysis of Mileage Data

The PHMSA Liquid Annual Data for the years 2010 and higher were filtered so that they represented infrastructure mileage for onshore liquids pipelines. Further filters were applied so that mileage data could be broken down by year of installation.

4.2.3.5.2 Calculation of Failure Frequency

To express pipeline incident frequency in a manner that is independent of timeframe or length of infrastructure, failure frequency estimates are conventionally expressed in normalized terms, using units of failures per mile per year of operation. To provide results in such normalized terms, this was calculated as follows:

Equation 17

$$FF_R = \frac{I_R}{L \times A}$$

Where,

- FF_R = Failure frequency (ruptures/mi.yr)
- I_R = Incident count obtained from the PHMSA flagged hazardous liquids incident database 2010–present (# ruptures)
- L = Average length of infrastructure in miles (i.e., infrastructure length values averaged over the PHMSA Liquid Annual Data for the years 2010 and higher)
- A = Number of years of incident data represented by the PHMSA flagged hazardous liquids incident database (for the "2010–present" database used, this value was 6 years)

Based on the above analysis, the failure frequency for Materials Defects was determined to be 2.775×10^{-06} ruptures/mi-yr.

4.2.3.6 Construction Defects

Construction defects failures are those that are attributed to construction or installation defects, such as girth weld defects.

The threat of construction defects does not lend itself to failure frequency estimation using a reliability approach due to the lack of a limit state model that is supported by probability distributions for its input parameters. Therefore, the approach that was used to estimate the frequency of occurrence for this threat applies a failure frequency derived from industry failure statistics for modern (1980 installation or later) pipeline materials, design, and installation practices.

4.2.3.6.1 Failure Frequency for Construction Defects

The PHMSA Hazardous Liquids incident database (2010–present, current to December 31, 2015) was sorted and failure frequency was calculated as described in Section 4.2.3.5.1. Once the above filters were applied, the number of ruptures that were associated with construction defects over the reporting period were counted.

Based on this analysis, the failure frequency for construction defects was determined to be 5.551×10^{-06} ruptures/mi- yr.

4.2.3.7 Incorrect Operations

Failures due to incorrect operations are related to human error and procedural error during the operation of a pipeline. The threat of incorrect operations failures does not lend itself to failure frequency estimation using a reliability approach due to the lack of a limit state model that is supported by probability distributions for its input parameters. In consideration of this fact, estimates of failure frequency were based on operating incident data related to this threat, modified by the results of the operations questionnaire that was administered during the Threat Assessment Workshop. This approach is similar to that described in the second edition of API RP 581 "Risk Based Inspection Technology", where operations-related failure frequency is obtained by multiplying a baseline operations-related failure rate by a management systems adjustment factor, as highlighted below:

Equation 18

$$FF_{IO} = FF_{IO,\,Baseline} \times AF_{MS}$$

Where,

FF_{IO}	= Incorrect operations failure frequency (ruptures/km yr)
$FF_{IO,\,Baseline}$	= Baseline rupture frequency for incorrect operations derived from industry failure statistics
AF_{MS}	= Operational Management Systems Adjustment Factor (0.1 – 10.0)

4.2.3.7.1 Baseline Failure Frequency for Incorrect Operations

The PHMSA Hazardous Liquids incident database (2010–present, current to December 31, 2015) was sorted and failure frequency was calculated as described in Section 4.2.3.5.1. Once the above filters were applied, the number of ruptures that were associated with incorrect operations over the reporting period were counted. Included in that count were all first and second party external interference incidents, since failures associated with first and second party damage can be considered as principally related to process failure and human error.

Based on this analysis, the failure frequency for incorrect operations was determined to be 2.775×10^{-06} ruptures/mi- yr.

4.2.3.7.2 Operational Management Systems Adjustment Factor

During the threat assessment, an operations questionnaire was administered. That questionnaire covered topics that were intended to gauge the performance of Enbridge operations in terms of the causal factors of failures related to incorrect operations. As detailed in the threat assessment, the results of the questionnaire were evaluated and scored, resulting in a score of 65 out of a possible 73 points (i.e., 89.0%).

Adopting the quantitative failure frequency estimation approach of API RP 581, an operational management systems adjustment factor is derived in accordance with the following expression:

Equation 19

$$AF_{MS} = 10^{[-0.02P_{Score}+1]}$$

Where,

P_{Score} = the percent score obtained on the Operations Questionnaire.

Based on a P^{Score} value of 89.0%, AFMS was determined to be 0.166.

From Equation 18, the adjusted incorrect operations rupture frequency was therefore determined to be 4.607×10^{-07} ruptures/km yr.

4.2.3.8 Geotechnical / Hydrotechnical Threat

To assess the degree of threat that a pipeline will be exposed to threats associated with geotechnical and hydrological factors, an evaluation of these factors was completed at each of the seven modeling locations. The review included published information (textbooks and reports), including soils maps, topographic maps, hydrological maps, pipeline alignment sheets, and incident reports related to ground movement, hydrological and geological events and floods.

A full description of the approach that was adopted for the determination of failure frequency is provided in Attachment A.

Failure likelihood estimates, expressed in terms of annual rupture probability were derived for each geohazard or hydrotechnical hazard identified at each site. The combined annual probability of pipeline rupture for all threats was then determined as the statistical "OR" function of all probability values associated with each threat for each site. The combined annual probability of rupture associated with geohazards / hydrotechnical hazards for each site is summarized in Table 4-17.

Table 4-17 Geohazard / Hydrotechnical Hazard Annual Probability of Rupture

Site	Annual Rupture Probability
1—Mosquito Creek	0.000
2—Mississippi River at Ball Club	5.000×10^{-08}
3—Sandy River	5.000×10^{-09}
4—Shell River	1.105×10^{-07}
5—Red River	1.050×10^{-07}
6—Mississippi River at Palisades	6.000×10^{-08}
7—Mississippi River at Little Falls	6.000×10^{-08}

4.2.4 Summarized Estimates of Failure Frequency

In Section 4.1, threat-specific estimates of failure frequency were provided for each unique combination of design variables associated with the L3RP at each of the seven modeling locations. Knowing the failure frequency associated with a given segment of pipeline (expressed in units of failures per mile per year of operation), the annual probability of failure over that segment length can be determined as:

Equation 20

$$P_f = 1 - (1 - FF)^{SL}$$

Where,

Pf = Annual probability of failure over a defined segment of length SL (miles)
FF = Failure Frequency (failures per mile per year of operation)

For multiple threats, the combined annual probability of failure is expressed as:

Equation 21

$$P_{Comb} = P_{f,Threat1} \, U \, P_{f,Threat2} \, U \, P_{f,Threat3} \ldots U \, P_{f,Threatn}$$

Where the operator U represents the statistical "OR" function.

From the above relationships, a summary of annual failure probability values for each of the seven modeling locations is provided for all threats identified in the threat assessment based on the threat-specific failure frequency values identified in Section 4.1. Results are provided below for each modeling site.

4.2.4.1 Mosquito Creek

The threat-specific failure annual probability of failure values for the L3RP at the Mosquito Creek modeling site are provided in Table 4-18.

Table 4-18 Failure Probability Summary L3RP, Mosquito Creek

Threat	Annual Failure Frequency (ruptures/mi.yr)	Segment Length (mi)	Annual Rupture Probability
External corrosion	1.000×10^{-08}	0.346	3.460×10^{-09}
Internal corrosion	1.000×10^{-08}		3.460×10^{-09}
Third party damage	1.026×10^{-06}		3.549×10^{-07}
Manufacturing defects	2.775×10^{-06}		9.602×10^{-07}
Construction defects	5.551×10^{-06}		1.921×10^{-06}
Incorrect operations	4.607×10^{-07}		1.594×10^{-07}
Geotechnical/hydrological forces	-		0.000
All threats combined			**3.402×10^{-06}**

4.2.4.2 Mississippi River at Ball Club

The threat-specific failure annual probability of failure values for the L3RP at the Mississippi River at Ball Club modeling site are provided in Table 4-19.

Table 4-19 Failure Probability Summary L3RP, Mississippi River at Ball Club

Threat	Annual Failure Frequency (ruptures/mi.yr)	Segment Length (mi)	Annual Rupture Probability
External corrosion	1.000×10^{-08}	0.039	3.900×10^{-10}
Internal corrosion	1.000×10^{-08}		3.900×10^{-10}
Third party damage	6.680×10^{-08}		2.605×10^{-09}
Manufacturing defects	2.775×10^{-06}		1.082×10^{-07}
Construction defects	5.551×10^{-06}		2.165×10^{-07}
Incorrect operations	4.607×10^{-07}		1.797×10^{-08}
Geotechnical/hydrological forces	-		5.000×10^{-08}
All threats combined			**3.961×10^{-07}**

4.2.4.3 Sandy River

The threat-specific failure annual probability of failure values for the L3RP at the Sandy River modeling site are provided in Table 4-20.

Table 4-20 Failure Probability Summary L3RP, Sandy River

Threat	Annual Failure Frequency (ruptures/mi.yr)	Segment Length (mi)	Annual Rupture Probability
External corrosion	1.000×10^{-08}	0.218	2.180×10^{-09}
Internal corrosion	1.000×10^{-08}		2.180×10^{-09}
Third party damage	6.680×10^{-08}		1.456×10^{-08}
Manufacturing defects	2.775×10^{-06}		6.050×10^{-07}
Construction defects	5.551×10^{-06}		1.210×10^{-06}
Incorrect operations	4.607×10^{-07}		1.004×10^{-07}
Geotechnical/hydrological forces	-		5.000×10^{-09}
All threats combined			**1.939×10^{-06}**

4.2.4.4 Shell River

The threat-specific failure annual probability of failure values for the L3RP at the Shell River modeling site are provided in Table 4-21.

Table 4-21 Failure Probability Summary L3RP, Shell River

Threat	Annual Failure Frequency (ruptures/mi.yr)	Segment Length (mi)	Annual Rupture Probability
External corrosion	1.000×10^{-08}	0.482	4.820×10^{-09}
Internal corrosion	1.000×10^{-08}		4.820×10^{-09}
Third party damage	6.680×10^{-08}		3.220×10^{-08}

5.0 MODELING OF OIL RELEASES

This chapter contains a description of the computational models used for different scenarios (Sections 5.1.1 and 5.1.2, respectively), the key assumptions made for these simulations (Section 5.2), and the input data sources, processing, and assumptions for environmental and chemical data (Section 5.3). Trajectory and fates results are presented in Chapter 6.0; results are organized by location, then type of crude oil and season.

Hypothetical oil releases from the proposed preferred and alternate pipeline routes for the L3RP were modeled using the OILMAP Land and SIMAP computation models that have been developed by RPS. The L3RP route is depicted in Figure 5-1.

Large releases of crude oil were simulated from five representative release locations along the pipeline using the OILMAP Land computation model. Two additional locations were selected for more comprehensive three dimensional modeling using the SIMAP modeling system. Modeling of large releases of crude oil at these seven locations provided quantitative predictions of the trajectory and fate of released oil under a range of environmental conditions (in-stream flows and seasons) and a range of crude oils (i.e., light and heavy crude oils). The rational for the selection of the two computational models; and the selection of a specific modeling system for different locations, are provided in Chapter 3.0. Details are also provided on the criteria used to select preferred locations for modeling of large releases of crude oil; how a specific range of conditions were determined for each hypothetical release (i.e., volume of the release, flow conditions, types of crude oil); and the types of output desired.

Information on the trajectory and fate of crude oil for these hypothetical releases was used to assess a wide range of potential effects on key receptors under different seasonal flows conditions and with light and heavy crude oils. The assessment of potential environmental effects included site-specific assessments of potential effects on environmentally-sensitive areas (e.g., HCAs and AOIs; Section 7.3), and on key receptors at each of the seven modeling locations (Sections 7.4 to 7.10).

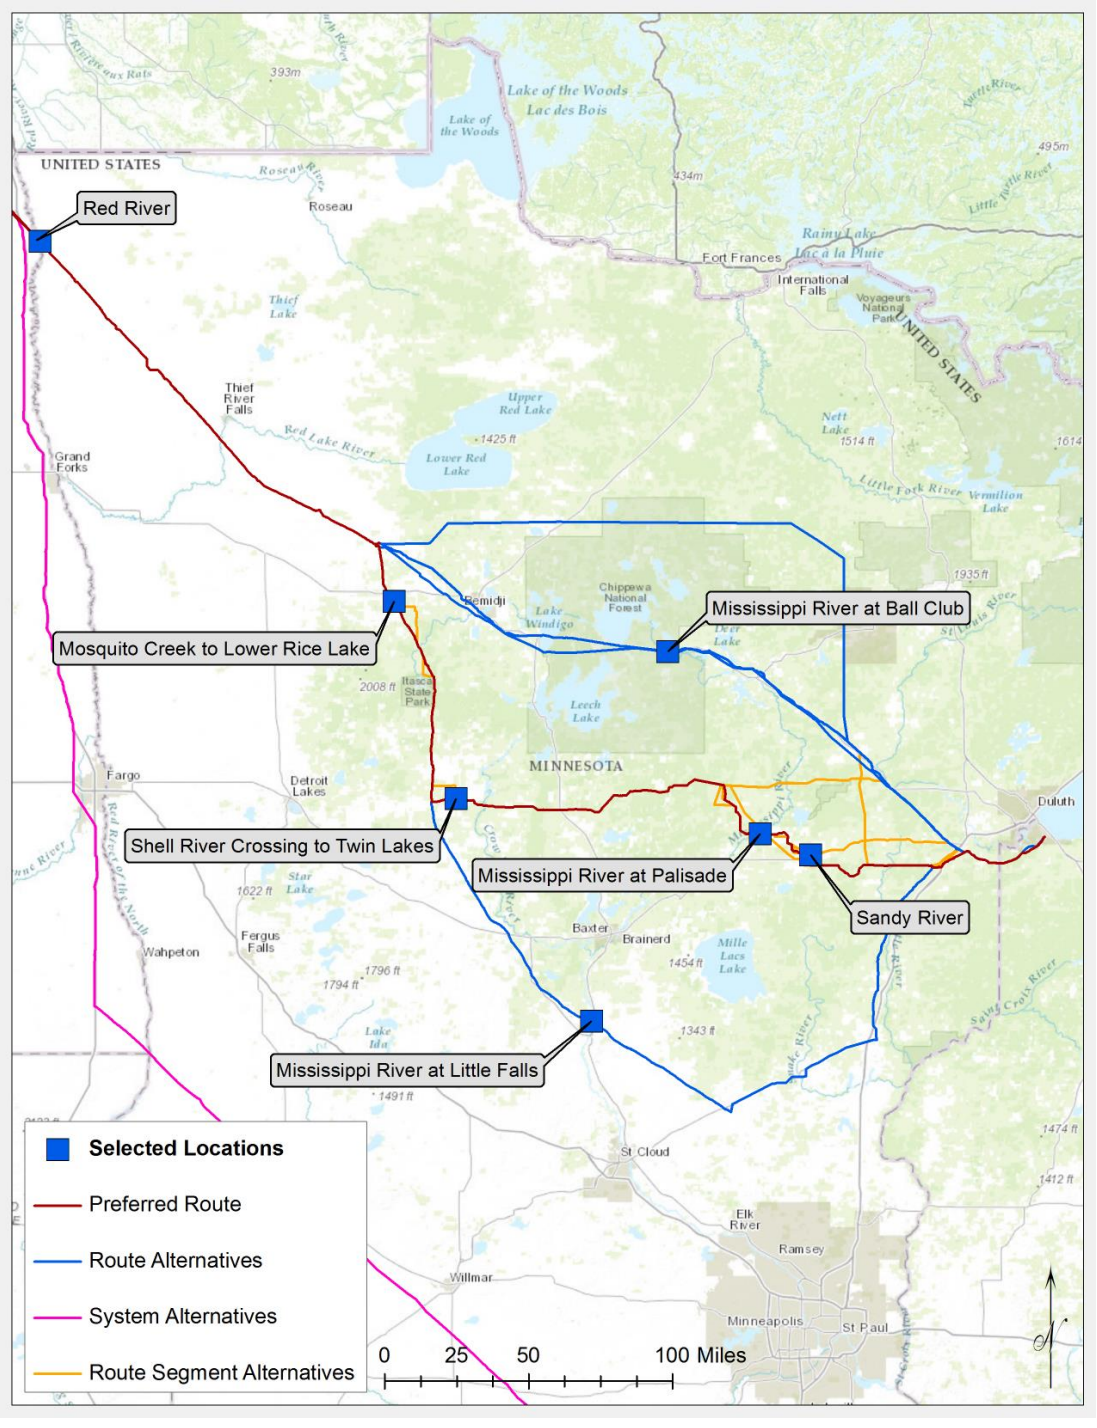

Figure 5-1 Map of the Enbridge Line 3 Replacement Pipeline Route, Preferred and Alternative Routes, and Selected Hypothetical Release Locations for Modeling

Of note, seasonal variations in river flow rate, temperature, wind speed, and snow and ice cover are expected at each of the modeled locations and would affect the trajectory and fate of a crude oil release. Because river discharge controls the downstream velocity of water and, therefore, the potential transport of oil, a hydrologic analysis was conducted to characterize seasonal differences at each hypothetical release location. Historical stream discharge (flow) data was used to determine the monthly average flow rate for each location. The seasonally appropriate environmental conditions that would be present during each of these months were then identified for use in modeling. The combination of multiple environmental conditions and oil types modeled at each location provide a realistic range of anticipated seasonal conditions upon which to base the hypothetical release scenarios. The three seasons modeled bound the range of likely conditions spanning high to low river flow rate, temperature, ice cover, and wind speed.

Months representing the average, maximum, and minimum river flow rates were identified, and the corresponding temperatures and wind speeds during those seasons were used in the modeling. The average monthly river flow rate month was considered representative of baseline conditions. As mean flow can occur in two seasons, typically observed around summer and fall, the month with the warmest temperature (i.e., August) was selected to represent the maximum amount of evaporation, potentially resulting in the largest exposure to hydrocarbon vapors in air as a potential trigger for human health effects. The month with the highest flow rate represented the spring freshet (i.e., a spring thaw and increased river flow rates from snow and ice melt typically occurring between April and June), a result of rising temperatures and snowmelt. The month with the lowest flow rate represented the winter (i.e., January–March), and was typified by freezing conditions and probable snow cover on land and ice cover on water.

5.1 DESCRIPTION OF MODELING TOOLS

The OILMAP Land modeling system was used to predict the trajectory and fate of hypothetical large releases of crude oil at five modeling locations: Mosquito Creek to Lower Rice Lake, Mississippi River at Ball Club, Sandy River, Shell River to Twin Lakes, and Red River (Table 3-5).

5.1.1 OILMAP Land

The OILMAP Land model simulates the flow of oil or chemicals from a given rupture point along a pipeline (Figure 5-2). The release is modeled as it propagates over the land surface and then into any surface water network until the entire amount of product is released. Oil flow over land is governed by the physical characteristics and slope of the land surface. The overland model calculates an oil mass balance that includes losses from oil adhesion to land over the oiled path, the formation of small puddles, oil pooling in large depressions on the land surface, and oil evaporation to the atmosphere.

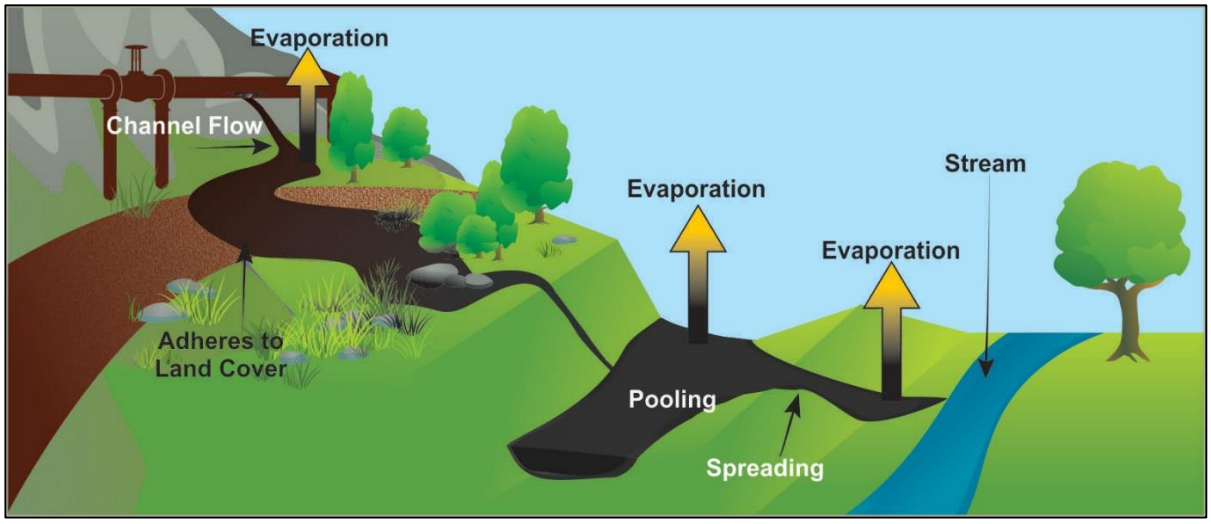

Figure 5-2 Conceptual Diagram of the Land Transport Model Depicting the Possible Fate of Oil as it Moves Over the Land Surface in OILMAP Land

In many cases, oil may reach a watercourse. The flow of oil within a watercourse is governed by surface currents, which require a different modeling approach (Figure 5-3). The water transport model simulates the downstream movement of oil on the water surface in streams at a defined velocity. As oil moves downstream, estimates of the amount of oil lost to the shore from adhesion and to the atmosphere by evaporation are made. Any oil entering a lake is allowed to spread over the water surface of the lake in a radial pattern to a minimum thickness that reflects the density and viscosity of the released oil.

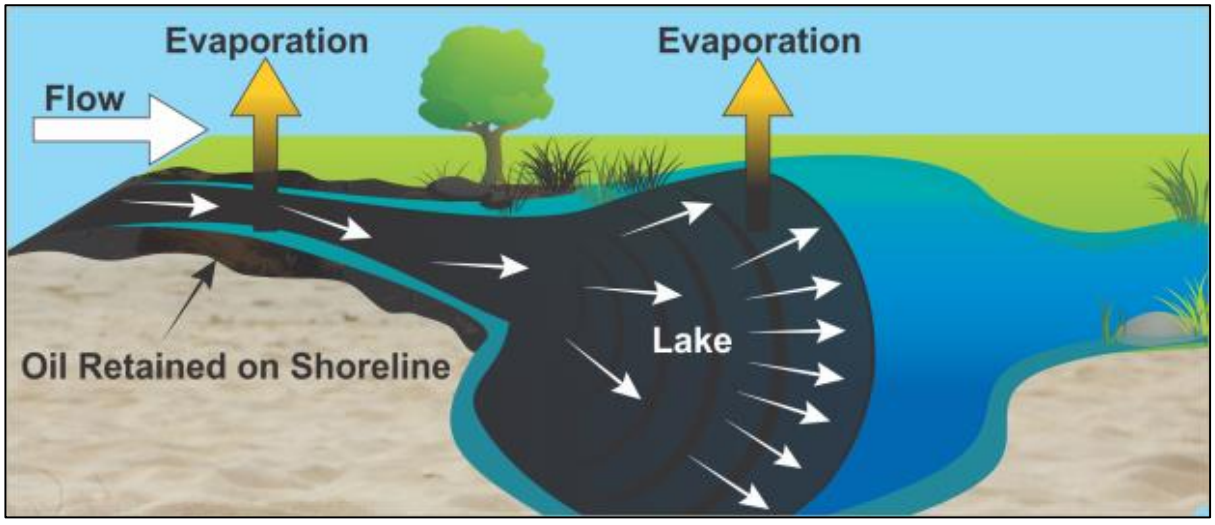

Figure 5-3 Conceptual Diagram of the Downstream Transport Model Depicting the Possible Fate of Oil Entering the Surface Water Network in OILMAP Land

While OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled 24-hour period, it is not able to provide detailed predictions of 3-D oil fate and transport. Therefore, complex processes such as entrainment of oil into the water column, dissolution of soluble fractions of hydrocarbons, and emulsion formation were not modeled for the five hypothetical release sites that were simulated with the OILMAP Land system. Two additional release locations on the Mississippi River were modeled using SIMAP to characterize a more comprehensive investigation of 3-D trajectory and fates process within the water column (Section 5.1.1.5).

5.1.1.1 Overland Release Model

For the purpose of the OILMAP Land computational model, the overland flow of oil is simulated using a square land elevation grid. Starting at the release location, the model searches the eight neighboring cells to determine the steepest down slope direction. The adjacent cell with the lowest elevation becomes the next starting location (Figure 5-4). This process repeats successively until a flat or depression area is reached. In a flat area, the model searches (i.e., looks beyond adjacent cells) to determine the minimum distance path to a next lowest cell. In a depression area, the area assumed to fill with liquid until the elevation of the surface of the pool equals the elevation of a grid cell on its boundary. At this point the boundary of the pool is breached, and the grid cell becomes the next starting point for farther down slope movement of oil. The lowest elevation cell becomes the next starting location.

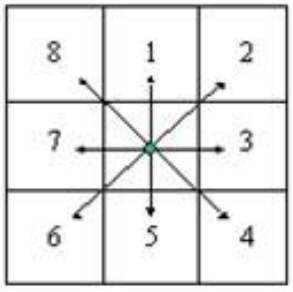

Figure 5-4 Diagram Showing How the OILMAP Land Model Searches the Eight Neighboring Cells to Determine the Steepest Down Slope Gradient and Resulting Direction of Flow

As a release path is established, the release area is calculated and the loss of oil is computed as a function of three process terms (i.e., adherence, pooling, and evaporation; Figure 5-2). Adherence, or depression storage, is the process by which oil is lost to the ground surface and vegetation as it spreads overland. Depression storage values vary by land type (as a function of surface area, roughness, etc.) and oil type (as a function of viscosity). Depression storage represents both the puddling of oil within small surface depressions on a scale smaller than the elevation grid, and physical adhesion of oil on surfaces. Pooling is larger-scale process by which oil is trapped within depressions in the local topography (i.e., depressions that can be resolved at the resolution of the available elevation grid). Such depressions are assumed to fill with oil

before additional down slope transport occurs. Evaporation is the process by which the volatile portion of the liquid oil becomes a gas that enters the atmosphere.

In the first calculation, the rate of oil loss to adhesion and puddle formation is dependent primarily on the physical characteristics of the land surface (vegetation type, land cover, slope) and the physical and chemical characteristics of the released product. A data grid specifying land cover type is used to determine the amount of oil retention on each grid cell. As oil traverses the land, a variable loss rate is calculated based upon changes in land cover type. Oil retention loss values vary by land type and oil type, with values spanning five orders of magnitude (between 0.02 and less than 200 mm) (Table 5-1). These loss rates for oil are based on surface hydrologic studies (ASCE 1969; Kouwen et al. 2002; Schwartz et al. 2002). The puddling or depression storage portion of the rate of oil loss represents the loss of oil based upon predicted sub-elevation grid scales within a grid cell, as elevation may have some heterogeneity within the scale of a single elevation grid cell.

Land cover was only used in the Mosquito Creek scenarios, as oil was assumed to enter directly into the river channels at the other four modeling locations for the OILMAP Land computational modeling. In the Mosquito Creek scenarios, a 0.5 mile stretch of grassland/herbaceous cover (during spring through fall) or snow/ice land cover (during winter months) extended downslope from the hypothetical release site to the waters of Mosquito Creek. Snow would retain a larger proportion of oil, than the grassland/herbaceous ground cover. A more complete description of the effects of snow cover may be found in Section 5.3.2.5.

Table 5-1 Range of Oil Retention Values for Each Land Cover Type, for a Light and Heavy Oil

OILMAP Land Code	Description	Light Oil (mm)	Heavy Oil (mm)
19	Unknown—data gaps, cloud cover, etc.	0.6	3.8
31	Bare rock/sand/clay	0.7	4.5
41	Deciduous forest	2.0	13.4
42	Evergreen forest	2.0	13.4
43	Mixed forest	2.0	13.4
51	Shrubland	0.6	3.8
71	Grasslands/herbaceous	0.6	3.8
82	Row crops	0.6	3.8
91	Woody wetlands	33.8	225.4
92	Emergent herbaceous wetlands	33.8	225.4
97	Tundra	0.7	4.5
98	Barren land	0.7	4.5
99	Snow/ice	*see section 5.2	

Table 5-1 Range of Oil Retention Values for Each Land Cover Type, for a Light and Heavy Oil

OILMAP Land Code	Description	Light Oil (mm)	Heavy Oil (mm)
103	Wetland	33.8	225.4
108	Impervious Surface	0.02	0.2

The second loss calculation includes oil lost to pooling on the land surface. This is defined as the volume of oil that would be retained within depressions defined by the land elevation grid. Released oil would need to fill the calculated volume of the depression before any additional oil would be allowed to travel downslope. When combined, the oil lost to the ground is the sum of adhesion, puddling and pooling.

The third loss calculation includes the evaporation of oil into the atmosphere. Evaporative loss is dependent upon the chemical and physical parameters of the oil, as well as the shape (i.e., surface area) of the release, and other environmental conditions. Some or all of the available/remaining released product may evaporate. The total amount of oil retention and loss during a release simulation includes both losses to the ground in addition to the evaporative loss to the atmosphere.

The leading edge of a release travels with a specific velocity (V), as the oil travels over the land surface. The velocity of the oil is determined using Manning's Equation, which uses the slope of the land surface and the width of the oil plume:

$$V = 1/n\ R^{2/3}\ S^{1/2}$$

Where R is the hydraulic radius and S is the slope, and n is a dimensionless number that characterizes the flow resistance from surface roughness. The hydraulic radius is a slope dependent metric of cross sectional area of flow divided by the wetted perimeter. It is calculated iteratively at each time step and is based upon flow rate. Typically R is approximately 0.122 m, which corresponds with velocity calculation that is dependent upon slope alone:

$$V = 4.92\ S^{1/2}\ \text{(meter/sec)}$$

Down-slope speed never reaches more than a few meters per second and has a minimum of 0.001 m/s. The maximum advance rate is limited by the release rate of the released oil.

In many cases, the elevation grid defining the land surface is not of sufficient resolution to define channels that direct the path of the oil. The width of the flow path increases as the slope of the land surface decreases and downslope velocity slows. Conversely, the path width decreases to a narrower channel with increasing land surface slope and increasing downslope velocity. The

model uses the land surface slope to calculate the path width of the oil. It is typically around 1 m, and cannot exceed the dimension of the land elevation grid cells.

The total volume of oil loss is equal to the sum of adherence and puddling, pooled oil, and evaporation. If total oil loss equals the total release volume during overland flow, then the release is terminated at this point. If the release volume is not a limiting factor, release propagation over land terminates when the leading edge encounters a surface water feature, or when the model's set duration is reached (i.e., 24 hours for modeling described here).

As noted earlier, the total volume of oil loss on land was only applied to the Mosquito Creek scenarios. The remaining six sites involved immediate release of oil into water.

5.1.1.2 Surface Water Transport Model

For the purpose of the OILMAP Land computational model, once the released product encounters a surface water feature during the high flow in spring or the average flow in summer, it is transported through the surface water network at a velocity defined by the speed and direction of each stream segment. As oil is transported down the surface water network, there are two potential loss terms including adhesion of the released product to the stream shoreline and loss of the released product through evaporation to the atmosphere. The modeled portions of the downstream release model and the factors influencing a release in surface waters are illustrated in Figure 5-3.

During winter conditions, the surface water transport model assumes complete ice coverage (100% ice cover) of the water surface. Any oil that makes its way to the watercourse from a land spill is predicted to not enter the water body due to the coverage of ice. However, if a hypothetical release were to occur into the watercourse from an underground/underwater crossing then the model assumes all of the oil would enter into the water column itself. In this case, oil is assumed to rise through the water column and be trapped by the ice cover at the surface. The model assumes that evaporation is completely prevented (0% evaporation) due to the layer of ice on the water surface.

For the winter modeling scenarios, it is assumed that the speed of the downstream transport of oil within river sections is at the same speed as the local water velocity. However, oil is assumed to pool under the ice in lakes, due to the lower velocity. These conservative approximations maximize the extent of potential oiling. A more complete description of the effects of ice cover may be found in Section 5.3.2.6.

The distance oil is allowed to travel downstream during any season is limited by one of three factors, including:

- Adherence of all available released product on the water surface to the stream bank as shoreline oiling
- Loss of all available /remaining released product to evaporation

- Reaching a user-specified travel time limit (i.e., model duration)

User-specified travel times are typically defined in release response plans as the time required to respond to a catastrophic release. Note that the model may not run for the full user-specified travel time limit (i.e., in the case of the modeling for L3RP this was 24 hours) if either of the second two criteria are met before this point.

The amount of oil adhering to the stream shoreline varies according to the stream shore type and oil type. Five different stream shore types were defined, each with a specified bank width and range of oil retention thickness, based upon the type of oil (Table 5-2). Oil volume lost to the shoreline is calculated as the product of the length of the shoreline oiled, the specified bank width, and the oil retention thickness, which is controlled by the density and viscosity of the oil.

Table 5-2 Typical Shoreline Oil Loss Values in Oil Thickness

Shore Type	Shore Width (m)	Light Oil (mm)	Heavy Oil (mm)
Bedrock	0.5	1	4
Soil	1	2	15
Sand/Gravel	2	3	20
Grass	5	4	25
Marsh	20	6	40

Oil movement across lakes is simulated based on lake size, shape, and water flow characteristics. Oil is assumed to spread radially across the lake surface until it covers the entire lake, or until the oil slick reaches a specified minimum thickness. If the minimum thickness is reached, spreading stops and the oil travels no farther. The minimum slick thickness is dependent upon the oil type, as density, viscosity, and other chemical and physical parameters control the behavior of oil on the water surface. Typical values for minimum slick thickness range from microns (µm) to millimeters (mm). In the case of the OILMAP Land computational model, if oil covers the entire lake surface before reaching the minimum thickness, the remaining oil is allowed to continue to move down any out-flowing streams at the velocity defined for that specific stream segment.

Dissolution—the process where water-soluble components of oil diffuse out of the oil and into the water—is not addressed by the OILMAP Land computational model. Dissolution is considered by SIMAP; accordingly this modeling system was used for the two modeling locations on the larger sections of the Mississippi River where dissolution and entrainment of oil was identified as a concern.

5.1.1.3 Evaporation in Overland and Surface Water Models

Evaporation is the process where volatile components of the oil diffuse out of the oil and enter a gaseous phase in the atmosphere. Oil evaporates as it spreads over land and water. The most volatile hydrocarbons (i.e., those having a low carbon number) evaporate most rapidly, typically in less than a day and sometimes in under an hour (McAuliffe 1989). As oil evaporates its composition changes, affecting its density and viscosity, as well as subsequent evaporation. As lighter components evaporate off, the remaining "weathered" oil becomes more viscous. As the oil continues to weather and, particularly, if it forms a water-in-oil emulsion, evaporation will be substantially decreased.

OILMAP Land uses a method called the Evaporative Exposure Model[8] of Stiver and Mackay (1984), which is used in oil release models of all kinds, both water and land based, to predict the volume fraction evaporated.

Several simplifying assumptions are made in modeling that directly affects the amount of oil predicted to evaporate. In general, the rate of evaporation depends on surface area, oil thickness, and vapor pressure, which are functions of the composition of the oil, wind speed, and air and land temperature. The mass of oil evaporated is particularly sensitive to the surface area of the spreading oil and the time period over which evaporation is calculated. On the land surface, the exposed surface area and evaporation time are functions of the slope, which is defined by the elevation grid. Steeper slopes cause the oil to travel faster but along a narrower path, while a lower slope slows the speed of advance and increases the width of the oiled path. In general, evaporation from surface and shoreline oil increases as the oil surface area, temperature, and wind speed increase.

In the stream network, the surface area of oiled water is a function of the total length of the oiled reach of the stream, times the average width of the same reach. The total length oiled is a function of stream velocity. The surface area of the oil surface then defines the rate of evaporation. Oil loss to evaporation is assumed to continue until the simulation is terminated. Termination may occur for a number of reasons, including:

- Oil loss to the ground surface, stream banks, and evaporation exceeds the volume released
- Release reaches its minimum thickness on a lake surface
- Release reaches either a dead end in the stream network or the coastline
- User-specified travel time limit (i.e., model duration) is reached

[8] The Evaporative Exposure Model of Stiver and Mackay (1984) is used to determine the rate of evaporation for spills of hydrocarbons and petroleum mixtures. The model uses the specified oil type's physical and chemical characteristics to determine the rate of evaporation, which includes the initial boiling point, the gradient of the distillation curve (i.e., the relationship between the oils liquid temperature and the fraction of oil condensed), and relationships between Henry's Law Constant, along with environmental parameters including temperature and wind speed.

In reality, oil will continue to evaporate from the ground or water surface, increasing the total evaporation amount. This conservative calculation of evaporative loss used in the OILMAP Land modeling system is consistent with a worst-case scenario approach.

For a release on the water surface, the gravitational spreading of the released oil occurs very rapidly (within hours) to a minimum slick thickness. Thus, the area exposed to evaporation is high relative to the oil volume. Evaporation proceeds faster than dissolution. Thus, most of the volatiles and semi-volatiles evaporate, with a smaller fraction dissolving into the water.

Evaporation is faster as the wind speed increases. However, above about 12 knots (6 m/s) of wind speed and in open water, white caps begin to form and the breaking waves entrain oil as droplets into the water column. Higher wind speeds (and turbulence) increase entrainment and results in smaller droplet sizes. These fates processes are not captured in the OILMAP Land model. More sophisticated (3D) modeling of oil transport and fate such as SIMAP take these factors into account.

5.1.1.4 Use of the OILMAP Land Modeling System for the L3RP

OILMAP Land was used for five of the seven modeling locations to predict the trajectory and fate of a large release of crude oil under different seasonal flow conditions and with different types of crude oil. The modeled scenarios did not include any response activities (i.e., unmitigated). The OILMAP Land modeling system was used to predict the expected downstream extent of oil transport (i.e., maximum downstream distance of a release at a specific time period) and the predicted mass balance of oil over the first 24 hours following the hypothetical release, including time steps at 6 and 12 hours. The mass balance reflects the amount of shoreline retention, evaporation, and oil remaining on the water surface over the first 24 hours following a release, or until no further oil is predicted to remain on the river surface (i.e., all oil is predicted to have evaporated or adhered to shorelines before 24 hours had passed). If there was oil on the river surface after 24 hours and the release was left unmitigated, it would continue downstream, and would continue to oil shorelines and evaporate until no oil remained. As an emergency response would be initiated soon after a release, the 24 hour time limit is considered appropriate and consistent with the conservative approach taken in this assessment.

5.1.1.5 Uncertainties in the OILMAP Land Modeling System

The OILMAP Land model is a simplified modeling system that was developed over many years to provide a conservative approximation of the maximum extent and maximum shoreline oiling that may be possible in the event of a release. However, there are limits to the complexity of processes that are modeled, as well as gaps in the underlying data that were used. As has been discussed, some simplifications have been made regarding steady-state currents and the behavior of oil on water and under ice. Additionally, the model does not take into account the influence of wind on the transport of oil on water. There is a degree of uncertainty related to the

terrain, as these datasets do not contain the full-scale horizontal resolution (i.e., <1 cm) that may affect an actual release. Furthermore, the assumptions of 100% shoreline oil retention and land retention values do err on the side of conservatism. Finally, the radial spreading of oil in lakes is a simplification that would err on the side of maximum surface oiling and maximum extent. While OILMAP Land may simplify real world releases, results from several actual releases on land compared well to the modeled predictions (Fontenault 2015; and other unpublished work).

5.1.2 SIMAP

The SIMAP modeling system was used to predict the trajectory and fate of hypothetical large releases of crude oil at two modeling locations on the Mississippi River: Mississippi River at Palisade and Mississippi River at Little Falls (Table 3-5).

The SIMAP modeling system was developed by RPS. It originated from the oil fate and biological effects submodels in the NRDA Models for Coastal and Marine Environments (NRDAM/CME) and Great Lakes Environments (NRDAM/GLE), which ASA developed in the early 1990s for the U.S. Department of the Interior for use in "type A" NRDA regulations under the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA). The most recent version of the type A models, the NRDAM/CME (Version 2.4, April 1996) was published as part of the CERCLA type A NRDA Final Rule (Federal Register, May 7, 1996, Vol. 61, No. 89, p. 20559-20614). The technical documentation for the NRDAM/CME is in French et al. (1996). This technical development involved several in-depth peer reviews, as described in the Final Rule.

While the NRDAM/CME and NRDAM/GLE were developed for simplified natural resource damage assessments of small releases in the U.S., SIMAP is designed to evaluate fate and effects of both real and hypothetical releases in marine, estuarine, and freshwater environments worldwide. Additions and modifications to SIMAP were made to increase model resolution, allow modification and site-specificity of input data, allow incorporation of spatially and temporally varying current data, evaluate subsurface releases and movements of subsurface oil, track multiple chemical components of the oil, enable stochastic modeling, and facilitate analysis of results.

The fates and effects models in the SIMAP modeling system are described below. Detailed descriptions of the algorithms and assumptions in the model are provided in French McCay 2002, 2003, 2004, and 2009. The model has been validated with more than 20 case histories, including the Exxon Valdez and other large releases (French and Rines 1997; French McCay 2003 and 2004; French McCay and Rowe 2004), as well as test releases designed to verify the model (French et al. 1997).

SIMAP estimates the distribution of whole oil and oil components (as mass and concentrations) on the water surface, on shorelines, in the water column, and in sediments. Oil fate processes in SIMAP are oil spreading (gravitational and by shearing), evaporation, transport, randomized dispersion, emulsification, entrainment (natural and facilitated by dispersant), dissolution,

volatilization of dissolved hydrocarbons from the surface water, adherence of oil droplets to suspended sediments, adsorption of soluble and sparingly-soluble aromatics to suspended sediments, sedimentation, and degradation.

Oil is a mixture of hydrocarbons of varying physical, chemical, and toxicological characteristics. Thus, oil hydrocarbons have varying fates and effects on organisms. In the SIMAP model, oil is represented by component categories, and the fate of each component is tracked separately. The "pseudo-component" approach (Payne et al. 1984 and 1987; French et al. 1996; Jones 1997; Lehr et al. 2000) is used, where chemicals in the oil mixture are grouped by physical-chemical properties, and the resulting component category behaves as if it were a single chemical with characteristics typical of the chemical group.

The most toxic components of oil to aquatic organisms are low molecular weight aromatic compounds (monoaromatic and polycyclic aromatic hydrocarbons, MAHs and PAHs), which are both volatile and soluble in water. Their acute toxic effects are caused by non-polar narcosis, where toxicity is related to the octanol-water partition coefficient (Kow), a measure of hydrophobicity. The more hydrophobic the compound, the more toxic it is likely to be. However, as Kow increases, the compound also becomes less soluble in water, so there is less exposure to aquatic organisms. The toxicity of compounds with log (Kow) values greater than about 5.6 is limited by their very low solubility in water and consequent low bioavailability (French McCay 2002; Di Toro et al. 2000). Thus, the potential for acute effects is the result of a balance between bioavailability, toxicity once exposed, and duration of exposure. French McCay (2002) contains a full description of the oil toxicity model in SIMAP. French McCay (2003, 2009) describes the implementation of the toxicity model in SIMAP.

Because of these considerations, the SIMAP fates model focuses on tracking the lower molecular weight aromatic components divided into chemical groups based on volatility, solubility, and hydrophobicity. In the model, the oil is treated as comprising eight components (Table 5-3).

Table 5-3 Definition of Four Distillation Cuts and the Eight Pseudo-Components in SIMAP (MAHs; benzene + toluene + ethybenzene + xylene, BTEX; PAHs)

Characteristic	Volatile and Highly Soluble	Semi-Volatile and Soluble	Low Volatility and Slightly Soluble	Residual (non-volatile and very low solubility)
Distillation cut	1	2	3	4
Boiling point (°C)	< 180	180–265	265–380	> 380
Molecular weight	50–125	125–168	152–215	> 215
Log (K_{ow})	2.1–3.7	3.7–4.4	3.9–5.6	> 5.6
Aliphatic pseudo-components: number of carbons	volatile aliphatics: C4 - C10	semi-volatile aliphatics: C10 - C15	low-volatility aliphatics: C15 - C20	non-volatile aliphatics: > C20
Aromatic pseudo-	MAHs:	2 ring PAHs: C4-	3 ring PAHs: C3-,	≥ 4 ring aromatics:

Table 5-3 Definition of Four Distillation Cuts and the Eight Pseudo-Components in SIMAP (MAHs; benzene + toluene + ethybenzene + xylene, BTEX; PAHs)

Characteristic	Volatile and Highly Soluble	Semi-Volatile and Soluble	Low Volatility and Slightly Soluble	Residual (non-volatile and very low solubility)
component name: included compounds	BTEX, MAHs to C3-benzenes	benzenes, naphthalene, C1-, C2-naphthalenes	C4-naphthalenes, 3-4 ring PAHs with log(K_{ow}) < 5.6	PAHs with log(K_{ow}) > 5.6 (very low solubility)

Six of the components (i.e., all but the two non-volatile residual components representing non-volatile aromatics and aliphatics) evaporate at rates specific to the pseudo-component. Solubility is strongly correlated with volatility, and the solubility of aromatics is higher than aliphatics of the same volatility. The MAHs are the most soluble, the two-ring PAHs are less soluble, and the three-ring PAHs slightly soluble (Mackay et al. 1992). Both the solubility and toxicity of the non-aromatic hydrocarbons are much lower than for the aromatics, and dissolution (and water concentrations) of non-aromatics is safely ignored. Thus, dissolved concentrations are calculated only for each of the three soluble aromatic pseudo-components.

This number of components provides sufficient accuracy for the evaporation and dissolution calculations, particularly given the time frame (minutes) over which dissolution occurs from small droplets and the rapid resurfacing of large droplets. The alternative approach of treating oil as a single compound with empirically-derived rates (e.g., Mackay et al. 1980; Stiver and Mackay 1984) does not provide sufficient accuracy for environmental effects analyses because the effects to water column organisms are caused by MAHs and PAHs, which have specific properties that differ from the other volatile and soluble compounds. The model has been validated both in predicting dissolved concentrations and resulting toxic effects, supporting the adequacy of the use of this number of pseudo-components (French McCay 2003).

The lower molecular weight aromatics dissolve from the whole oil and are partitioned in the water column and sediments according to equilibrium partitioning theory (French et al. 1996; French McCay 2004). The residual fractions in the model are composed of non-volatile and insoluble compounds that remain in the "whole oil" that spreads, is transported on the water surface, strands on shorelines, and disperses into the water column as oil droplets or remains on the surface as tar balls. This is the fraction that composes black oil, mousse, and sheen.

5.1.2.1 Oil Fate Model Processes

Because oil contains many chemicals with varying physical-chemical properties and the environment is spatially and temporally variable, the oil rapidly separates into different phases or parts of the environment; specifically:

- Surface oil

- Emulsified oil (mousse) and tar balls
- Oil droplets suspended in the water column
- Oil adhering to suspended particulate matter in the water
- Dissolved lower molecular weight components (MAHs, PAHs, and other soluble components) in the water column
- Oil on and in the sediments
- Dissolved lower molecular weight components (MAHs, PAHs, and other soluble components) in the sediment pore water
- Oil on and in the shoreline sediments and surfaces

The oil fate processes simulated by SIMAP in near shore and riverine environments are shown schematically in Figure 5-5.

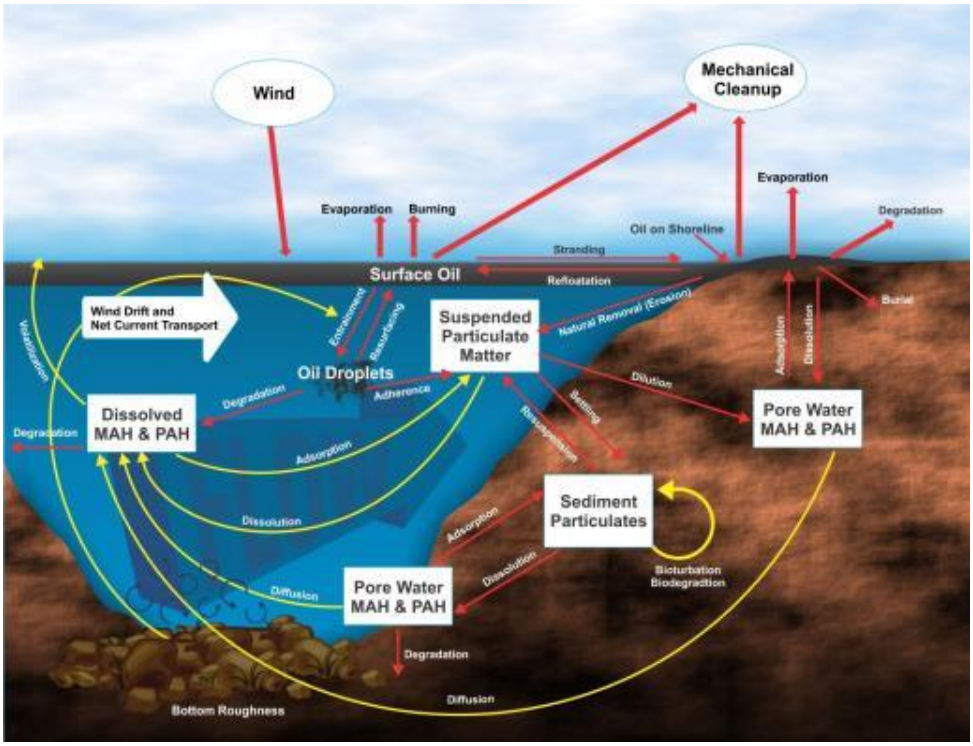

Figure 5-5 Oil Fates Processes in Lakes and Rivers That are Simulated by SIMAP

- **Spreading** is the thinning and broadening of surface slicks caused by gravitational forces and surface tension. This occurs rapidly after oil is released on the water surface. The spreading rate is faster when oil viscosity is lower at higher temperatures. Viscosity increases as oil emulsifies.
- **Transport** is the process where oil is carried by currents.
- **Turbulent dispersion** is the process by which turbulence ("sub-scale" currents that mix oil in three dimensions) spreads oil components on the surface and into the water column.

- **Evaporation** is the diffusion of volatile compounds from oil into a gaseous phase in the atmosphere. Evaporation from surface and shoreline oil increases as the oil surface area, temperature, and wind speed increase. As lighter components evaporate, the remaining "weathered" oil becomes more viscous.
- **Emulsification** is the mixture of water into the oil, such that the oil forms a matrix with embedded water droplets. The resulting mixture is commonly called mousse, which is technically a water-in-oil emulsion. The rate of emulsification increases with increasing wind speed and turbulence on the surface of the water. Viscosity increases as oil emulsifies.
- **Entrainment** is the process by which waves break over surface oil and carry oil droplets into the water column. At higher wind speeds (about 12 knots, or 6 m/s) or where currents and bottom roughness induce turbulence in a river or stream, wave heights may reach a threshold where they break. Thus, entrainment becomes increasingly important (higher rate of mass transfer to the water) with higher wind speeds.
- **Resurfacing** of entrained oil occurs rapidly for larger oil droplets. Smaller droplets resurface when the wave turbulence decreases. The smallest droplets do not resurface, as typical turbulence levels in the water keep them indefinitely suspended. Local winds at the water surface can also prevent oil from surfacing.
- **Dissolution** is the diffusion of water-soluble components out of the oil and into the water. Dissolution rate increases as the surface area of the oil relative to its volume increases. Since the surface area to volume ratio is higher for smaller spherical droplets, smaller droplet sizes have higher dissolution rates.
- **Volatilization** of dissolved components from the water to the atmosphere occurs as they mix, diffuse to the water surface boundary, and enter the gas phase. Volatilization rates increase with increasing air and water temperature.
- **Adsorption** of dissolved components to particulate matter in the water occurs because the soluble components (MAHs and PAHs) preferentially adsorb to particulates when the latter are present. The higher the concentration of suspended particulates, the more adsorption occurs. Also, the higher the molecular weight of the compound, the less soluble it is, and the more it tends to adsorb to particulate matter.
- **Adherence** is combination of oil droplets with particles in the water. If the particles are suspended sediments, the combined oil/suspended sediment agglomerate is heavier than the oil and the surrounding water. If turbulence subsides, the oil-sediment agglomerates will settle.
- **Sedimentation (settling)** is the process where oil-sediment agglomerates and particles with adsorbed sparingly-soluble components (MAHs and PAHs) settle to the bottom sediments. Sedimentation can be an important oil pathway in near shore areas when waves are strong and subsequently subside. Generally, oil-sediment agglomerates transfer more PAHs to the bottom than sediments with PAHs adsorbed from the dissolved phase in the water column.
- **Resuspension** of settled oil-sediment agglomerates and particles with adsorbed sparingly-soluble components (MAHs and PAHs) may occur if current speeds and turbulence exceed threshold values for overcoming cohesive forces.
- **Diffusion** is the process where dissolved compounds move from higher to lower concentration areas by random motion of molecules and micro-scale turbulence. Dissolved components in bottom and shoreline sediments can diffuse out to the water column where concentrations are relatively low. Bioturbation, groundwater discharge, and hyporheic flow of water through stream-bed sediments can greatly increase the rate of diffusion from sediments (see below).
- **Hyporheic flow** is the movement of water through stream bed sediments, induced by pressure differentials associated with stream bed irregularities or groundwater discharge.

- **Dilution** occurs when water of lower concentration is mixed into water with higher concentration by turbulence, currents, or shoreline groundwater.
- **Bioturbation** is the process by which benthic fauna mix the surface sediment layer while burrowing, feeding, or passing water over their gills. In open-water soft-bottom environments with minimal or no pollution, bioturbation effectively mixes the top 10 cm of the sediment layer.
- **Degradation** is when oil components are changed either chemically or biologically (biodegradation) into another compound. Degradation occurs through breakdown to simpler organic carbon compounds by bacteria and other organisms, photo-oxidation by solar energy, and other chemical reactions. Higher temperature and higher light intensity (particularly ultraviolet wavelengths) increase the rate of degradation.
- **Stranding and refloatation** occur when floating oil meets the shorelines and then refloats as water levels rise, allowing the oil to move further down current or downstream.

5.1.2.2 Overview of Processes Affecting a Release of Oil

Following a release of oil on the water surface, gravitational spreading occurs very rapidly (within hours) to a minimum thickness. Thus, the area exposed to evaporation is high relative to the oil volume. Evaporation proceeds faster than dissolution. Thus, most of the volatiles and semi-volatiles evaporate, with a smaller fraction dissolving into the water. Degradation (photo-oxidation and biodegradation) also occurs at a relatively slow rate compared to these processes.

As mentioned previously, evaporation is faster as the wind speed increases. Above about 12 knots (6 m/s) of wind speed and in open water conditions, white caps begin to form and the breaking waves entrain oil as droplets into the water column. These processes are modeled in SIMAP and higher wind speeds (and turbulence) increase entrainment and results in smaller droplet sizes. From Stoke's Law, larger droplets resurface faster and form surface slicks. Thus, a dynamic balance evolves between entrainment and resurfacing. As high- wind events occur, the entrainment rate increases. When the winds subside to less than 12 knots, the larger oil droplets resurface and remain floating. Similar dynamics occur in turbulent streams.

The smallest oil droplets remain entrained in the water column for an indefinite period. Larger oil droplets rise to the surface at varying rates. While the droplets are under water, dissolution of the light and soluble components occurs. Dissolution rate is a function of the surface area available. Thus, most dissolution occurs from droplets, as opposed to from surface slicks, since droplets have a higher surface area to volume ratio, and they are not in contact with the atmosphere (and so the soluble components do not preferentially evaporate as they do from surface oil).

If oil is released or driven underwater, it forms droplets of varying sizes. The more turbulent the conditions, the smaller the droplet sizes. From Stoke's Law, larger droplets rise faster, and surface if the water is shallow. Resurfaced oil behaves as surface oil after gravitational spreading has occurred. The surface oil may be re-entrained. In most cases, the smallest droplets remain in the water permanently. As a result of the higher surface area per volume of small droplets, the dissolution rate is much higher from subsurface oil than from floating oil on the water surface.

Because of these interactions, the majority of dissolved constituents (which are of concern because of potential effects on aquatic organisms) are from droplets entrained in the water. For a given release volume and oil type/composition, with increasing turbulence either at the water surface and/or at the stream bed: there is an increasing amount of oil entrained; the oil is increasingly broken up into smaller droplets; there is more likelihood of the oil remaining entrained rather than resurfacing; and the dissolved concentrations will be higher. Entrainment and dissolved concentrations increase with (1) higher wind speed, (2) increased turbulence from other sources of turbulence (waves on a beach, rapids, and waterfalls in rivers, etc.), and (3) subsurface releases (especially under higher pressure and turbulence.

These processes that increase the rate of supply of dissolved constituents are balanced by loss terms in the model: (1) transport (dilution), (2) volatilization from the dissolved phase to the atmosphere, (3) adsorption to suspended particulate material (SPM) and sedimentation, and (4) degradation (photo-oxidation or biologically mediated). Other processes slow the entrainment rate: (1) emulsification increases viscosity and slows or eliminates entrainment, (2) adsorption of oil droplets to SPM and settling removes oil from the water, (3) and stranding on shorelines removes oil from the water. Thus, the model-predicted concentrations are the resulting balance of all these processes and the best estimates based on our quantitative understanding of the individual processes.

5.1.2.3 Oil Fate Algorithms

The algorithms used to model oil fate processes are described in French McCay (2004). Lagrangian elements (spillets) are used to simulate the movements of oil components in three dimensions over time. Within the model, releases of oil are broken down into many thousands of discrete or individual elements (i.e., Lagrangian Elements referred to as spillets) that are forced and tracked individually throughout the modeled domain. Surface floating oil, subsurface droplets, and dissolved components are tracked in separate spillets. Transport is the sum of advective velocities based on the input on watercourse currents to the model, surface wind drift, vertical movement according to buoyancy, and randomized turbulent diffusive velocities in three dimensions. The vertical diffusion coefficient is computed as a function of wind speed in the surface wave-mixed layer. The horizontal and deeper water vertical diffusion coefficients are model inputs.

The model separates oil (whole and as pseudo-components [Section 5.1.2]) into different phases or parts of the environment. SIMAP considers: surface slicks; emulsified oil (mousse) and tar balls; oil droplets suspended in the water column; dissolved lower molecular weight components (MAHs and PAHs) in the water column; oil droplets adhered and hydrocarbons adsorbed to suspended particulate matter in the water; hydrocarbons on and in the sediments; dissolved MAHs and PAHs in the sediment pore water; and hydrocarbons on and in the shoreline sediments and surfaces.

The algorithms used to calculate these fates processes are briefly described in the subsections below.

5.1.2.3.1 Transport

Spillets are moved in three dimensions over time. For each model time step, the new vector position of the spillet center is calculated from the old location plus the vector sum of east-west, north-south, and vertical components of advective and diffusive velocities:

$$Xt = X\,t\text{-}1 + \Delta t\,(\,Ut + Dt + Rt + Wt\,)$$

where Xt is the vector position at time t, Xt-1 is the vector position the previous time step, Δt is the time step, Ut is the sum of all the advective (current) velocity components in three dimensions at time t, Dt is the sum of the randomized diffusive velocities in three dimensions at time t, Rt is the rise or sinking velocity of whole oil droplets in the water column, and Wt is the surface wind transport ("wind drift"). The magnitudes of the components of Dt are scaled by horizontal and vertical diffusion coefficients (Okubo and Ozmidov 1970; Okubo 1971). The vertical diffusion coefficient is computed, based on Thorpe (1984), as a function of wind speed in the surface wave-mixed layer (which ranges from centimeter scales in rivers and near lee shorelines to potentially meters in large water bodies away from shore when wind speeds are high). Rt is computed by Stokes law, where velocity is related to the difference in density between the particle and the water, and to the particle diameter. The algorithm developed by Youssef and Spaulding (1993) is used for wind transport in the surface wave-mixed layer (Wt, described below).

5.1.2.3.2 Shoreline Stranding

The fate of released oil that reaches the shoreline depends on characteristics of the oil, the type of shoreline, and the energy environment. The stranding algorithm is based on work by CSE/ASA/BAT (1986), Gundlach (1987), and Reed and Gundlach (1989) in developing the COZOIL model for the U.S. Minerals Management Service. In SIMAP, deposition occurs when an oil spillet intersects shore surface. Deposition ceases when the model determines that the volume holding capacity for the shore surface is reached. The model does not allow subsequent oil coming ashore to remain on the shore surface. It is assumed to be refloated by rising water, and carried away by currents and wind drift SIMAP then removes the remaining shoreline oil exponentially over time. Data for holding capacity and removal rate are taken from CSE/ABA/BAT (1986) and Gundlach (1987), and are a function of oil viscosity and shore type. The algorithm and data are provided in French et al. (1996).

5.1.2.3.3 Spreading

Spreading determines the areal extent of the surface oil which, in turn, influences its rates of evaporation, dissolution, dispersion (entrainment), and photo-oxidation, all of which are functions of surface area. Spreading results from the balance among the forces of gravity, inertia, viscosity, and surface tension (which increases the diameter of each spillet). The model also considers two other processes that can influence the spreading of an oil release: turbulent

diffusion (which spreads the spillets apart); and entrainment followed by resurfacing, which can spatially separate the leading edge of the oil from resurfaced oil transported in a different direction by subsurface currents.

For many years, Fay's (1971) three-regime spreading theory was widely used in oil spill models (ASCE 1996). Mackay et al. (1980, 1982) modified Fay's approach and described the oil as thin and thick slicks. Their approach used an empirical formulation based on Fay's (1971) terminal spreading behavior. They assumed the thick slick feeds the thin slick and that 80–90% of the total slick area is represented by the thin slick. In SIMAP, oil spillets on the water surface increase in diameter according to the spreading algorithm empirically-derived by Mackay et al. (1980, 1982). Sensitivity analyses of this algorithm led to the discovery that the solution was affected by the number of spillets used. Thus, a formulation was derived to normalize the solution under differing numbers of surface spillets (Kolluru et al. 1994). Spreading is stopped when an oil-specific terminal thickness is reached.

5.1.2.3.4 Evaporation

The rate of evaporation depends on surface area, thickness, vapor pressure, and mass transport coefficient which, in turn, are functions of the composition of the oil, wind speed, and temperature (Fingas 1996, 1997, 1998, 1999; Jones 1997). As oil evaporates, its composition changes, affecting its density and viscosity, as well as subsequent evaporation. The most volatile hydrocarbons evaporate most rapidly, typically in less than a day and sometimes in under an hour (McAuliffe 1989). As the oil continues to weather, and particularly if it forms a water-in-oil emulsion, evaporation will be significantly decreased.

The evaporation algorithm in SIMAP is based on accepted evaporation theory, which follows Raoult's Law that each component will evaporate with a rate proportional to the saturation vapor pressure and mole fraction present for that component. The pseudo-component approach (Payne et al. 1984; French et al. 1996; Jones 1997; Lehr et al. 2000) is used, such that each component evaporates according to its mean vapor pressure, solubility, and molecular weight. The mass transfer coefficient is calculated using the methodology of Mackay and Matsugu (1973), as described in French et al. (1996).

5.1.2.3.5 Entrainment

As oil on the water surface is exposed to wind and waves, or if oil moves into a turbulent area of a stream or river, it is entrained (or dispersed) into the water column. Entrainment is a physical process where globules of oil are transported from the water surface into the water column due to breaking waves or other turbulence. It has been observed that entrained oil is broken into droplets of varying sizes. Smaller droplets spread and diffuse in the water column, while larger ones rise back to the surface.

5.1.2.3.5.1 Entrainment by Breaking Surface Wave Action

In open waters, breaking waves created by the action of wind and waves on the water surface are the primary sources of energy for entrainment. Entrainment is strongly dependent on turbulence and is greater in areas of high wave energy (Delvigne and Sweeney 1988).

Delvigne and Sweeney (1988), using laboratory and flume experimental observations, developed a relationship for entrainment rate and oil droplet size distribution as a function of turbulent energy level and oil viscosity. Entrained droplets in the water column rise according to Stokes law, where velocity is related to the difference in density between the particle and the water, and to the particle diameter. The data and relationships in Delvigne and Sweeney (1988) are used in SIMAP to calculate the mass and particle size distribution of entrained droplets. Particle size decreases with higher turbulent energy level and lower oil viscosity. The natural dispersion particle sizes observed by Delvigne and Sweeney (1988) are confirmed by field observations by Lunel (1993a, 1993b).

Entrained oil is mixed uniformly throughout the wave-mixed zone. Vertical mixing is simulated by random placement of particles within the wave-mixed layer each time step. Settling of particles does not occur in water depths where waves reach the bottom (taken as 1.5 times wave height). Wave height is calculated from wind speed, duration, and fetch (distance upwind to land), using the algorithms in CERC (1984). Wave height is on the scale of centimeters in small rivers and streams and near lee shorelines; whereas it may increase to meters in open waters under windy conditions.

5.1.2.3.5.2 Entrainment by Bottom Roughness in Streams

When modeling oil releases in rivers, entrainment of oil into the water column by turbulent flow over bottom structures and around obstacles must be taken into consideration. It is clear that in rapid flow where turbulence is large, rocks or other obstacles may break the surface and a plunging wake may occur where the possibility of entrainment increases. Delvigne (1993) demonstrated that breaking wave dispersion to fast flow past an obstacle, such as a pile, generates a plunging wake. This is sufficiently similar to breaking waves from alternative sources of turbulence such as the fast flow past an obstacle, flow over a dam, cataract with a hydraulic jump, or a vessel crossing an oil slick. In the breaking wave model, the dispersion of energy leads to the plunging of oil into water and the formation of oil droplets.

To relate this more generally to a river formulation, an energy dissipation relationship was developed. In this formulation, energy dissipation is proportional to the stream flow rate and bottom roughness, and is inversely proportional to the local depth. The generation and propagation of turbulent energy through the water column due to bottom roughness is applied with a typical quadratic stress equation to the plunging flow (Anderson et al. 1995). The dispersed mass of oil is determined by scaling the surface area covered by oil at the dispersion source and the range of oil droplet sizes, which is a function of the dispersion energy.

5.1.2.3.6 Emulsification (Mousse Formation)

The formation of water-in-oil emulsions, or mousse, depends on oil composition and turbulence level. Emulsified oil can contain as much as 80% water in the form of micrometer-sized droplets dispersed within a continuous phase of oil (Daling and Brandvik 1988; Fingas et al. 1997). Viscosities are typically much higher than that of the parent oil. The incorporation of water also dramatically increases the oil/water mixture volume.

SIMAP uses the Mackay and Zagorski (1982) emulsification scheme for floating oil. Water content increases exponentially, with the rate related to the square of wind speed and previous water incorporation. Viscosity is a function of water content. The change in viscosity feeds back in the model to the entrainment rate.

5.1.2.3.7 Dissolution

Dissolution is the process by which soluble hydrocarbons enter the water from a surface slick or from entrained oil droplets. The lower molecular weight hydrocarbons tend to be both more volatile and more soluble than those of higher molecular weight. For surface slicks, since the partial pressures tend to exceed the solubility of these lower molecular weight compounds, evaporation accounts for a larger portion of the mass than dissolution (McAuliffe 1989), except perhaps under ice. Dissolution and evaporation are competitive processes. The dissolved component concentration of hydrocarbons in water under a surface slick shows an initial increase followed by a rapid decrease after some hours due to the evaporative loss of components. Most soluble components are also volatile and direct evaporation (volatilization) from the water column depletes their concentrations in the water. Dissolution is a particularly important weathering process where evaporation is low (dispersed oil droplets and ice-covered surfaces). Dissolution can be substantial from entrained droplets because of the lack of atmospheric exposure and because of the higher surface area per unit of volume.

SIMAP uses the model developed by Mackay and Leinonen (1977) to calculate dissolution from a surface slick. The slick (spillet) is treated as a flat plate, with a mass flux (Hines and Maddox 1985) related to solubility and temperature. It assumes a well-mixed layer with most of the resistance to mass transfer lying in a hypothetical stagnant region close to the oil. For subsurface oil, dissolution is treated as a mass flux across the surface area of a droplet (treated as a sphere) in a calculation analogous to the Mackay and Leinonen (1977) algorithm. The dissolution algorithm was developed in French et al. (1996).

5.1.2.3.8 Volatilization from the Water Column

SIMAP uses the procedure outlined by Lyman et al. (1982), based on Henry's Law and mass flux (Hines and Maddox 1985) to calculate volatilization from the water column. The volatilization depth for dissolved substances is limited to the maximum of one half the wave height. Wave height is computed from the wind speed and fetch (CERC 1984). The volatilization algorithm was developed in French et al. (1996).

5.1.2.3.9 Adsorption and Sedimentation

Aromatics dissolved in the water column are carried to the sediments primarily by adsorption to suspended particulates and subsequent settling. The ratio of adsorbed (C_a) to dissolved (C_{dis}) concentrations is computed from standard equilibrium partitioning theory as:

$$C_a / C_{dis} = K_{oc} C_{ss}$$

K_{oc} is a dimensionless partition coefficient and C_{ss} is the concentration of SPM in the water column expressed as mass of particulate per volume of water. As a default, the model uses a mean value of total suspended solids of 10 mg/l (Kullenberg 1982); alternatively data on suspended sediment concentrations in a watercourse can be used as model input.

Sedimentation of oil droplets occurs when the specific gravity of oil increases over that of the surrounding water. Several processes may act on entrained oil and surface slicks to increase density: weathering (evaporation, dissolution and emulsification), adhesion or sorption onto suspended particles or detrital material, and incorporation of sediment into oil during interaction with suspended particulates, bottom sediments, and shorelines. Rates of sedimentation depend on the concentration of suspended particulates and the rates of particulate flux into and out of an area. In areas with high suspended particulate concentrations, rapid dispersal and removal of oil is found due to sorption and adhesion (Payne and McNabb 1984).

Kirstein et al. (1987) and Payne et al. (1987) used a reaction term to characterize the water column interactions of oil and suspended particulates. The reaction term represents the collision of oil droplets and suspended matter, accounting for both oiled and unoiled particulates. The model formulation developed by Kirstein et al. (1987) is used to calculate the volume of oil adhered to particles. In the case where the oil mass is larger than the adhered sediment (i.e., the sediment has been incorporated into the oil), the buoyancy of the oil droplet will control its settling or rise rate. Within SIMAP, the Stoke's law formulation is used to adjust the vertical position of these particles. If the mass of adhered droplets is small relative to the mass of the sediment it has adhered to, the sediment settling velocity will control the fate of the combined particulate.

5.1.2.3.10 Degradation

Degradation may occur as the result of photolysis or photo-oxidation, which is a chemical process energized by ultraviolet light from the sun, and by microbial breakdown, termed biodegradation. In SIMAP, degradation occurs on the surface slick, deposited oil on the shore, the entrained oil and aromatics in the water column, and oil in the sediments. SIMAP employs a first order decay algorithm, with a specified (total) degradation rate for each oil type: surface oil, water column oil, and sedimented oil (French et al. 1999).

5.1.2.4 The Application of SIMAP for Effects Assessment

For both of the Mississippi River locations that were modeled with SIMAP, multiple release scenarios were run to simulate the expected behavior of two oil types (Bakken crude or CLB/CLWB) under three seasonal and environmental conditions (high-, average-, and low-river

flow, representing spring, summer, and winter, respectively). This resulted in a total of 12 SIMAP trajectory and fates scenarios (2 locations x 2 oils x 3 seasons). The intent was to provide a range of representative trajectories and fates to understand the range of potential effects that may be anticipated under varying geographic and environmental conditions.

A deterministic modeling approach was used to provide a prediction of a representative individual release, based on specific parameters for each single event. The deterministic trajectory simulations provided representative estimates of the oil's fate and transport for a specific set of environmental conditions. Each scenario assumed that the total volume of released oil for the release location (Table 3-5) was released in a series of spillets over 10 minutes, where the trajectory, fate, and effects were tracked for the following 24 hours after the release. All modeled releases were assumed to be unmitigated, meaning that no response efforts were undertaken (e.g., booming, burning, skimming, collection).

The results of the deterministic simulations provide a time history of oil weathering (i.e., mass balance) over the 24 hour duration for the spill modeling, expressed as the percentage of released oil on the water surface, on the shoreline, evaporated, entrained in the water column, and decayed. In addition, times series snapshots of the individual trajectories showing location of floating surface oil, shoreline oil, and the concentration of dissolved aromatics in the water column (surface and profile view) are provided. Summary figures of results are provided for each combination of release location, oil type, and modeled season (Section 6.2).

As was discussed in the OIMLAP Land Application (Section 5.1.1), the SIMAP modeling results were used to assess potential environmental effects through two major methods: an overlay of the predicted trajectory of the oil release of HCAs and AOIs; and an assessment of effects on key receptors of the natural and human environment.

5.1.2.5 Uncertainties in the SIMAP Modeling System

The SIMAP model has been developed over many years to greatly increase the types and amount of information to simulate the fates and effects of oil releases. However, as in all science, there are limits to the complexity of processes that can be modeled, as well as gaps in knowledge regarding the environment that is affected. As described in the preceding sections, assumptions based on available scientific information and professional judgments were made in the development of the model.

The major sources of uncertainty in the oil fates processes considered by SIMAP are:

- Oil contains thousands of chemicals of differing physical and chemical properties that determine their fate in the environment. The model must of necessity treat the oil as a mixture of a limited number of components, grouping chemicals by physical and chemical properties.
- The fates model contains a series of algorithms that are simplifications of complex physical-chemical processes. These processes are understood to varying degrees.

- Information on physical parameters including but not limited to hydrodynamics, water depth, river width, total suspended solids concentration, and wind speed were based on the available data for the release location and the predicted downstream trajectory. When data was lacking, previous experience and sources from other similar locations were used to determine the parameter values that were implemented in the model. In some cases, professional judgment was required to make appropriate assumptions.

In addition, in the unlikely event of an actual oil release, the fates and effects will be strongly determined by the specific environmental conditions, and a myriad of details related to the event. Thus, the results are a function of the scenarios simulated and the accuracy of the input data used. The goal of the SIMAP modeling was not to forecast every detail that could potentially occur, but to describe a range of possible consequences so that an informed analysis could be made as to the likely effects of oil releases under various scenarios. The model inputs are designed to provide representative conditions to inform such an analysis for the scenarios considered.

5.2 KEY ASSUMPTIONS

The OILMAP Land and SIMAP modeling was based on a number of assumptions relating to the type of release event (i.e., full bore rupture, release of oil into watercourses), the volume of oil released, the duration of the release and subsequent downstream movement prior to mitigation (i.e., 24 hours), and the types of crude oil released. Each of these are discussed below.

5.2.1 Full Bore Rupture is an Unlikely Event

A full bore rupture means that the pipeline is severed or burst, such that the opening is equivalent to the cross-sectional area of the pipe (regardless of the mechanism leading to the rupture) and crude oil is assumed to spill freely from this opening. By design, and as a result of Enbridge's pipeline operation and maintenance programs (Enbridge 2014), a full bore rupture pipeline incident is considered to be a highly unlikely event. The selection of full bore, and the calculation of release volumes based on a full bore rupture, is therefore a highly conservative assumption.

5.2.2 Identification of Representative Hypothetical Release Scenarios

Even in the event of a full bore rupture incident, crude oil releases to land often result in only small areas of land (i.e., a few hectares) becoming contaminated by released oil. This is not to suggest that such effects would not be consequential. Rather, it justifies the selection of crude oil releases that enter watercourses (rivers or lakes) as being a conservative choice with respect to the fate, transport, and potential effects of released oil. With a larger spatial distribution, unmitigated releases of oil into water would have greater potential to cause adverse effects to larger numbers of ecological and human receptors. Therefore, this analysis focused on scenarios that result in the release of crude oil to watercourses as a conservative assumption.

Seven locations, each adjacent or close to a watercourse, were selected for modeling of hypothetical large releases of crude oil. The selection of these seven modeling locations was guided by consideration of the following engineering and environmental/socio-economic risk factors (Section 3.3.3):

- Located so that crude oil release volumes could potentially enter a watercourse; this included selection of locations where the hypothetical release of oil would either occur directly into a watercourse or would travel a short distance overland into a watercourse
- Located where shut-off valves would not overly restrict the volume of oil that could potentially be released (i.e., the hydraulic drain down of pipeline would be a substantial contributor to the oil release volume)
- Include sites along both the preferred and alternate routes
- Representative of the geographic and environmental conditions and land uses along the proposed ROW for the pipeline to allow for an evaluation of the range of potential effects to the natural and human environment along the pipeline
- Include a range of watercourse types (e.g., size, flow, energy level) and water bodies, including wetlands
- Support evaluation of potential effects to environmentally sensitive resources (e.g., spawning grounds for fish, wild rice lakes, or other sensitive habitats)
- Represent areas of expressed concern by Native American tribes, the general public, and/or state and federal agencies
- Support evaluation of potential effects to traditional use, other human use or infrastructure (e.g., potable water intakes or treatment facilities)

Based on a review of potentially sensitive hypothetical release locations and collaboration with the MN DNR and MN PCA (Sections 3.3.4 and 3.3.5), the scenarios were narrowed to seven general areas:

- Site 1—Mosquito Creek to Lower Rice Lake
- Site 2—Mississippi River at Ball Club
- Site 3—Sandy River
- Site 4—Shell River to Twin Lakes
- Site 5—Red River
- Site 6—Mississippi River at Palisade
- Site 7—Mississippi River at Little Falls

Modeling of hypothetical release scenarios at these seven locations was completed to predict the potential trajectory of released oil, the fate of released oil, and the potential effects of accidental oil releases on the natural and human environment. The intent of these analyses for each modeling location was to infer a range of potential effects that may occur at other locations in Minnesota with similar biophysical and human use characteristics.

5.2.3 Crude Oil Release Volume

At each of the seven identified potential release locations, the environmental effects of a hypothetical full-bore pipeline rupture were evaluated.

For each hypothetical release scenario, other than the Mosquito Creek land release, it was conservatively assumed that released oil would enter directly into the watercourse with no retention of oil on land. These circumstances would produce a scenario where most of the estimated volume of released crude oil would enter the aquatic environment close to the point of release. Making the assumption that the damage to the pipeline occurred near a topographic low point maximizes the hypothetical release volume (due to drain-down of the pipeline following the initial volume that was released under pressure before the pipeline was shut down), but also implies that the hypothetical release occurred in proximity to a watercourse. This is a conservative assumption, due to the potential for watercourses to effectively and rapidly transport released crude oil away from the release location.

The hypothetical release scenario is modeled such that a change in pipeline flow characteristics due to the rupture would be detected at the Control Center and the pipeline would be shut down (see next paragraph). For the purposes of this analysis, it is assumed that the location of the full-bore rupture would be at a low point (e.g., in proximity to a watercourse) between two control valves, and that oil would continue to drain by gravity from the pipeline, between the location of the rupture and the nearest valves.

The crude oil release volume was calculated as a full bore rupture, with a conservative response in the pipeline Control Centre of a maximum of 10 minutes, followed by a 3-minute period to allow for valve closure, and then drain-down of the elevated segments of pipeline. The maximum 13-minute duration of Control Center response time to valve closure is a standard for safe operations and leak detection for Enbridge. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown and full valve closure in the affected pipeline section. While 13 minutes is the maximum time, this is a conservative assumption, since a response through to valve closure would be expected to occur in less than 13 minutes in a full bore rupture leak scenario.

The maximum volume of oil that could be hypothetically released at each site was determined based on the pipeline specifications and topographic conditions in proximity to each modeling location; the maximum volume out included both the initial release volume prior to shutdown (i.e., actively pumping out), as well as hydraulic drain down of the pipeline (i.e., gravity drained oil within the pipeline between the valves), following shutdown at that site. The maximum volume of oil that could hypothetically be released from the L3RP at each modeling location is summarized in Table 3-5.

The release duration is the amount of time required for the released oil volume to be released from the ruptured pipeline, including drain-down. The OILMAP Land and SIMAP modeling systems use a constant release rate based upon the defined total release volume and duration of release. The release duration was calculated using the release volume, pipeline diameter, pipeline shutdown time, pipeline design flow rate, and elevation profile of the pipeline.

5.2.4 24 hour Unmitigated Oil Release

The analysis was carried out following a highly conservative assumption that the release would be unmitigated for 24 hours, and that the released crude oil would travel downstream unimpeded for that length of time. This is a conservative assumption because Enbridge would immediately mobilize a response that would contain and collect oil in the event that a release were to be detected. The 24-hour time frame is consistent with guidance from the USEPA, which stipulates a 27-hour period, representing 24-hours for arrival and 3-hours for deployment (USEPA 2003). As such, modeled results should not be interpreted as representative of expected effects, but rather as an unlikely, unmitigated worst-case potential outcome.

Crude oil release simulations that reach the 24 hour time limit may still have oil remaining on the surface of the river or lake that has not adhered to a shoreline or spread to the defined minimum thickness. If there was oil on the water surface after 24 hours, it could (if not mitigated) continue to move downstream, further oiling shorelines until it either evaporated or stranded. The simulations assumed the releases were unmitigated for the modeled 24 hour period (i.e., no benefits of emergency response operations were incorporated into the model). In a real-life scenario, emergency response procedures would mitigate the effects of the modeled incidents.

5.2.5 Crude Oil Types

The range of product types expected to be shipped in the L3RP may range from light crude oils such as those in the Alberta Light Sweet Crude category, to heavy oils such as conventional heavy crude oils and diluted bitumen products. The physical and chemical characteristics of light and heavy crude oils are quite different, although the characteristics of diluted bitumens are very similar to those of heavy conventional crude oils (Zhou et al. 2015). Therefore, two crude oil types were selected for their representative characteristics and conservatively high potential for effects to serve as the basis for the analysis. The two oil types include Bakken Crude Oil (a light conventional crude oil with a high aromatic content) and CLB (a diluted bitumen). The characteristics of these oils are detailed in Section 5.3.1 of this document.

5.3 INPUT DATA SETS

5.3.1 Oil Property Data

A range of product types are expected to be shipped in the L3RP pipeline, including heavier oils such as diluted bitumen and lighter oils such as Alberta Light Sweet Crude light crudes, with similar product characteristics to Bakken oils. The chemical and physical characteristics of these oil types are quite different. To account for these differences, two representative product types were selected for this modeling assessment that bound the range of anticipated products that may be shipped: the heavier diluted bitumen CLB and the lighter Bakken Crude oil. The differences between these oils will result in a range of potential outcomes related to the trajectory, fate, and effects of releases under varying environmental conditions.

CLB is a diluted bitumen with a high viscosity and density, falling in the upper range of characteristic values allowed by the pipeline tariff specifications for Enbridge. This product exhibits generally mid-range density and viscosity characteristics for the range of diluted bitumen products. Seasonal variations in environmental temperatures affect the viscosity of the diluted bitumen, which directly affects the ability to pump the fluid through the pipeline. To address this, the amount of diluent added to Cold Lake bitumen is varied through the year to attain a viscosity that meets shipping requirements. The largest amount of diluent is added to the bitumen during winter to reduce the viscosity to a level suitable for shipping at low temperatures. As a consequence, the density, viscosity, and aromatic content changes through the year. During the winter months, CLB has a lower density and viscosity and a greater aromatic content, when compared to the summer months.

As the chemical and physical characteristics of the CLB will vary seasonally, CLSB and CLWB were considered in the modeling of hypothetical releases. CLSB was used for spring and summer scenarios, while the CLWB was used for winter scenarios.

Bakken Crude Oil is produced in North Dakota, Montana, and the bordering Canadian provinces of Manitoba and Saskatchewan. Bakken crude is a light crude oil with an API gravity generally between 40° and 43° and a sulfur content less than 0.2 wt.%. Bakken is a relatively light crude oil with low density, low viscosity, and a high aromatic content.

The chemical and physical characteristics of each representative product, including chemical and physical properties, were derived from publicly available data from Environment Canada's Oil Properties database, technical data reports, assays, and other related project work (Enbridge 2014; S.L. Ross 2010; ESTC 2016; Exxon Mobil 2015; CrudeMonitor 2016). The level of detail, including the type of variables and number of analytes measured did vary between data sources. When specific oil property data was not available, the properties from similar oil types were assumed (ESTC 2016). For all three oils, minimum oil slick thicknesses were determined based on Coastal Response Research Center categories and observations of releases compiled by RPS ASA (2013) and the previous work of Allen and Dale (1997), McAuliffe (1987), NRC (1985, 2002) and the Bonn Agreement (Daling et al. 1999).

5.3.1.1 Physical Properties of the Oils

The physical properties of the three crude oils considered in modeling of hypothetical releases at each of the seven modeling locations are shown in Table 5-4.

Table 5-4 Physical Properties of the Three Crude Oils

Oil Property	Bakken Crude	Cold Lake Winter Blend	Cold Lake Summer Blend
Oil Type	Crude	Emulsion	Emulsion
Minimum Slick Thickness (µm)	0.1	10.0	10.0

Table 5-4 Physical Properties of the Three Crude Oils

Oil Property	Bakken Crude	Cold Lake Winter Blend	Cold Lake Summer Blend
Surface tension (dyne/cm)	27.3	27.1	27.1
Pour Point (°C)	-55.0	-45.0	-45.0
API Gravity	41.80	22.69	20.73
Density (g/cm^3) at 16°C	0.81650	--	--
Density (g/cm^3) at 15°C	--	0.91770	0.92950
Viscosity (cP) at 10°C	3.88	--	--
Viscosity (cP) at 15°C	--	150.0	342.0
Viscosity (cP) at 30°C	2.49	--	--

5.3.1.2 Chemical Properties of the Oils

The chemical properties of CLB were estimated using information from the Crude Monitor (2016) for the period of 2009 through 2016 (Figure 5-6). Seasonal variations in the fractional composition of the whole oil was used to determine volume of BTEX and the total hydrocarbon concentration (THC), by pseudo-component, of CLWB and CLSB. These results provide the variability and ultimately the ratio of BTEX and THC between winter and summer blends. BTEX concentrations (modeled as AR1) that were measured directly for the Exxon Mobil (2015) assay were used for CLWB, and the ratio of winter to summer calculated from Crude Monitor (2016) was used to scale BTEX values for the CLSB. Additional aromatic concentrations (AR2 and AR3) for CLWB were available from direct measurements for the S.L. Ross (2010) assay. For CLSB, the winter to summer ratio was used to scale the S.L. Ross (2010) values for AR2 and AR3. The total hydrocarbon breakdown (THC1, THC2, and THC3) for CLWB was determined from distillation data (Exxon Mobil 2015). The aliphatic breakdown (AL1, AL2, and AL3) was calculated by difference (e.g., AL1 = THC1 – AR1). For CLSB, the THC was again scaled based upon the winter to summer ratio from Crude Monitor (2016). Together, this analysis provides a breakdown of the chemical composition of CLB by pseudo-component for the winter and summer blends.

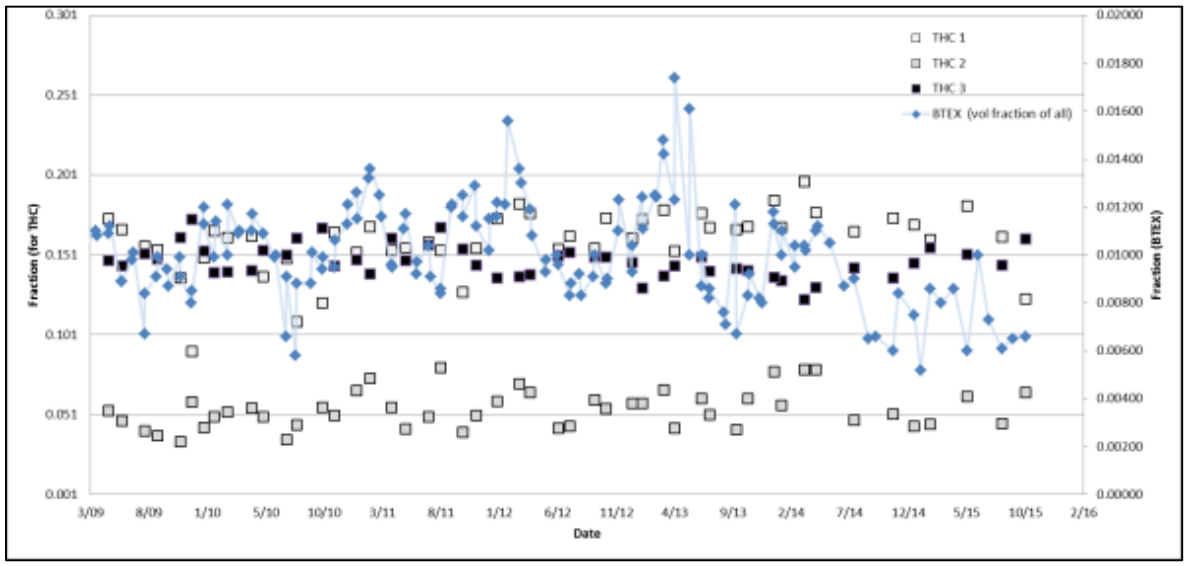

Figure 5-6 Fractional Composition of the THC and BTEX (AR1) Components in CLB from 2009 through 2016 (CrudeMonitor 2015)

The aromatic, aliphatic, and total hydrocarbon concentration and percentage composition of fresh whole oil for the three crude oils considered in modeling of hypothetical releases at each of the seven modeling locations are shown in (Table 5-5). BTEX content peaks in winter month blends and can make up greater than 1.6% of the fractional volume of the whole oil.

Table 5-5 Aromatic (AR), Aliphatic (AL), and Total Hydrocarbon Concentration (THC) and Percentage Composition of Fresh Whole Oil for the Three Crude Oils

Oil Type	Oil Component	% AR	% AL	% THC[1]
Bakken Crude	**1** (AR = BTEX & MAHs >C8-C10) (AL = >C6-C10)	0.029300	0.250700	0.280000
	2 (AR = MAHs and PAHs >C10-C12) (AL= >C10-C12)	0.022045	0.167955	0.190000
	3 (AR = PAHs >C12-C16) (AL = >C12-C16)	0.037668	0.242332	0.280000
Cold Lake Winter Blend	**1** (AR = BTEX & MAHs >C8-C10) (AL = >C6-C10)	0.012460	0.213302	0.225762
	2 (AR = MAHs and PAHs >C10-C12) (AL= >C10-C12)	0.000880	0.059265	0.060145
	3 (AR = PAHs >C12-C16) (AL = >C12-C16)	0.004400	0.136629	0.141029
Cold Lake	**1**	0.009003	0.154127	0.163130

Table 5-5 Aromatic (AR), Aliphatic (AL), and Total Hydrocarbon Concentration (THC) and Percentage Composition of Fresh Whole Oil for the Three Crude Oils

Oil Type	Oil Component	% AR	% AL	% THC[1]
Summer Blend	(AR = BTEX & MAHs >C8-C10) (AL = >C6-C10)			
	2 (AR = MAHs and PAHs >C10-C12) (AL= >C10-C12)	0.000748	0.050367	0.051115
	3 (AR = PAHs >C12-C16) (AL = >C12-C16)	0.004300	0.133538	0.137838

NOTE:
[1] THC is the sum of AR and AL. (Numbers of carbons in the included compounds are listed, e.g., >C8-C10 indicates greater than 8 carbons and including 9- and 10-carbon hydrocarbons.)

In some cases, additives are combined with the oil to reduce drag or turbulence in a pipeline, allowing it to pump at lower pressure. Additives are mainly comprised of polymers, solid-particle suspensions, biological additives, and surfactants that serve as drag-reducing agents or polymers. These compounds make up only a very small portion of the total volume of shipped product (i.e., oil) moving through the pipeline and are measured at part-per-million (ppm) levels. Because of this, the ultimate trajectory, fate, and effects would not be significantly different between a crude oil with or without these agents. This modeling exercise did not take any additive substances into account.

5.3.2 OILMAP

5.3.2.1 Elevation Data

The OILMAP Land model uses land elevation data to determine the overland pathways of releases occurring in the terrestrial environment. The elevation data are stored in a grid (raster) format and the model calculates the down slope pathway by determining the direction of steepest slope, as the leading edge of the release moves from grid cell to grid cell.

The ability of the model to accurately determine the overland release pathways is in large part controlled by the vertical and horizontal resolution of the elevation grid.

The horizontal resolution refers to the size of the individual grid cells of the elevation data in north-south and east-west directions. As the horizontal resolution increases it is possible to include smaller terrain features in the elevation data in the OILMAP Land model. This may include roads, ditches, and other smaller-scale features. As each horizontal grid cell is assigned a single elevation value, small-scale features can be flattened or smoothed in the larger grid cell and have limited effects on the elevation, especially when the resolution of the horizontal elevation data is course.

The vertical resolution refers to the level of precision available for each cell's elevation value. Sub-meter precision is critical for accurate modeling of flow over a land surface. Without the small sub-meter variations in the elevation surface, larger areas of no apparent elevation change may be present. In this case, the surface flow model will have greater difficulty in determining an overland flow direction, as multiple cells need to be crossed to find the downslope gradient.

Elevation data was obtained from the U.S. Geological Survey (USGS) National Elevation Dataset (USGS 2015). These data have either a 1/3 arc second (approximately 32.8 ft [10 m]) or 1 arc second (approximately 98.4 ft [30 m]) horizontal resolution and were primarily used as a reference for the topography surrounding the various rivers modeled. The higher resolution data covered all portions of land within the U.S., while the coarser one arc second resolution data was used to define the small portion of Canadian land area north of the release location. Elevation data used for modeling was obtained from the MN DNR (MN DNR 2014). The elevation data used was a digital elevation model (DEM) that was derived from LiDAR data. The DEMs have a 9.8 ft (3 m) horizontal resolution and 0.4 in (1 cm) vertical resolution. The Accuracy of the raw LiDAR data is reported as less than 9.8 ft (1 m) in the horizontal and less than 5.9 in (15 cm) in the vertical. They were used in OILMAP Land overland modeling at the Mosquito Creek site and for the stream crossing analysis at all sites. Land elevation maps for all sites modeled in OILMAP Land are presented below (Figure 5-7 through Figure 5-11).

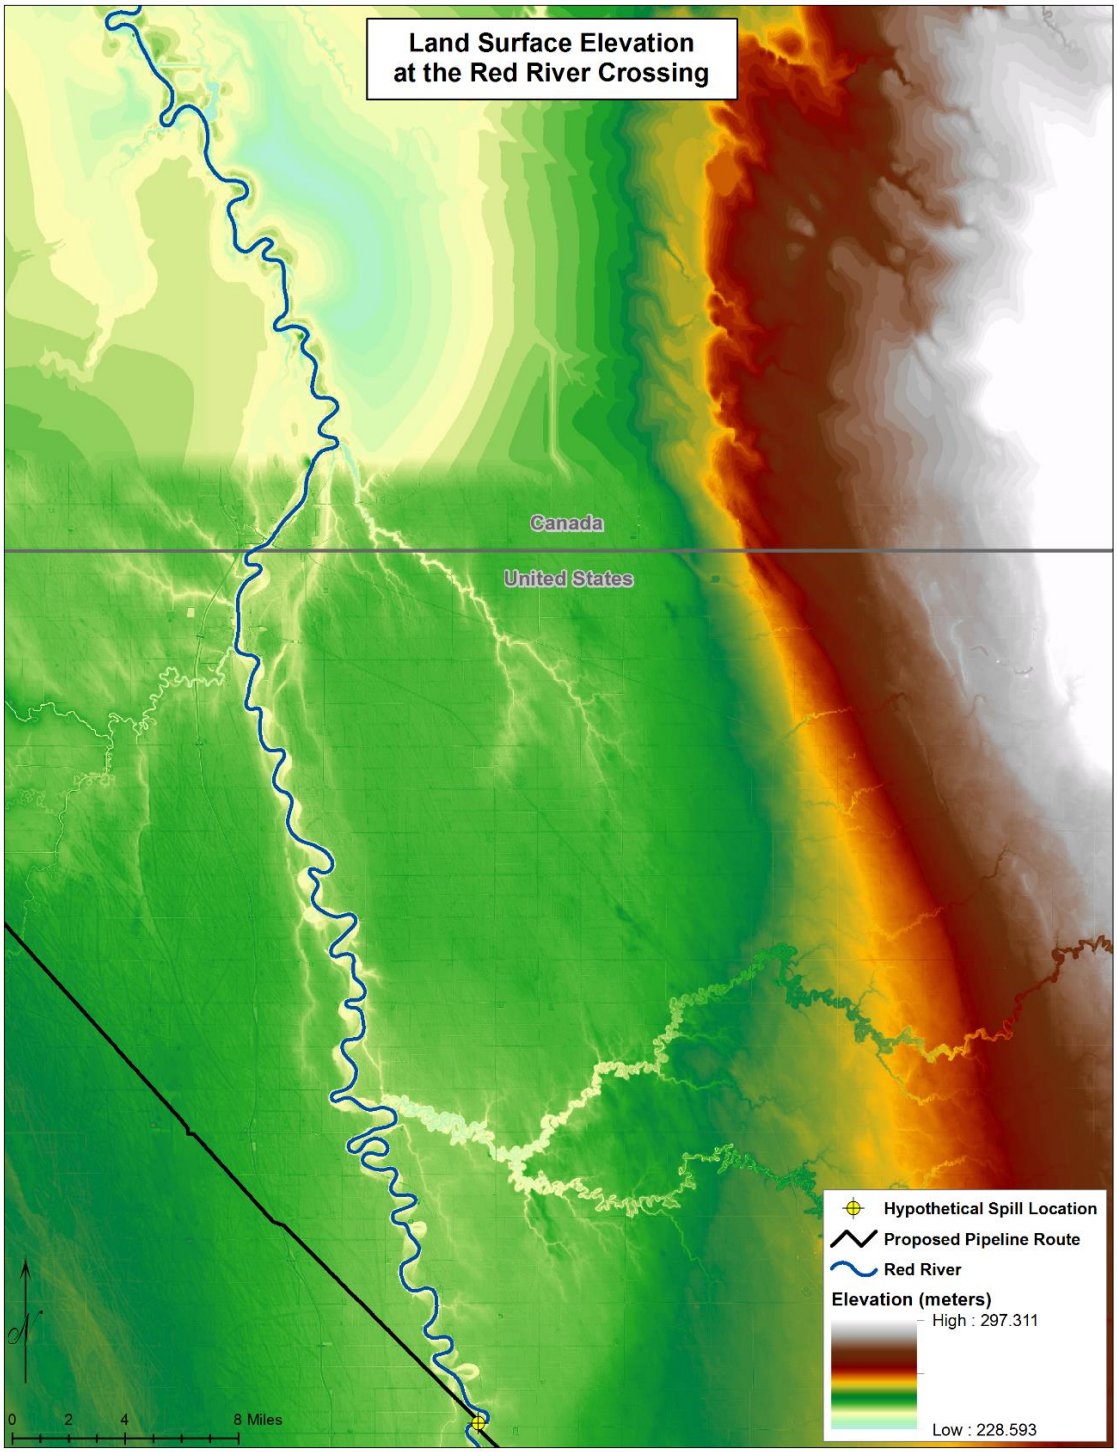

Figure 5-11 Land Surface Elevation (m) for the Red River Release Location. Elevation Data for Canadian Land is at a Coarser Resolution than the U.S.

5.3.2.2 Surface Water Data

The OILMAP Land release model uses data for networked streams and lakes to model the pathways of oil once it reaches surface water. Streams and rivers are represented in the model as a polyline feature of the stream centerline, which has been digitized according to the flow direction. The streams must be networked in a way such that the model can determine where each single stream segment joins the next, as the downstream movement of oil is modeled. Lakes are represented as polygon features, and connect to the streams that both feed and drain them, as appropriate.

Each individual stream segment has its own defined stream velocity and width. Therefore, the model calculates an appropriate downstream transport as a river or stream changes. As an example, a section of a river may widen and slow, and be followed by a narrower and faster reach. The OILMAP Land model uses the location specific river velocity to more accurately model the oil pathway and fate in the stream network.

Surface water data were derived from multiple sources. Stream centerlines, stream polygons and lake polygons were derived from the USGS high resolution National Hydrography Dataset (NHD) (USGS 2014). This data provides geospatial vector data, at a 1:24,000 scale, describing hydrographic features such as lakes, reservoirs, rivers, streams and canals in the form of a linear drainage network. Stream centerlines, networking, and flow information was used from the USEPA's NHDPlus version 2 data (NHDPlus v2; Horizon Systems 2012). NHDPlus integrates the USGS's medium resolution (1:100,00 scale) NHD, the 1/3 arc-second resolution National Elevation Database (NED), and National Watershed Boundary Dataset (WBD) to improve stream networking information, and estimate stream flow and velocity for every stream segment. Stream centerlines for the Canadian portion of the Red River were taken from the National Hydro Network (NHN) of Canada.

NHDPlus includes an estimated monthly and annual average stream flow rate and velocity for each stream segment. Flow is estimated using the Extended Unit Runoff Method (EROM). This method determines flow based on estimate of accumulated runoff based on the elevation data, evaporative loss, and various adjustments based on gages in the region. The velocities are calculated based on the estimated flow using the Jobson Method (Jobson 1996).

The Canadian NHN data does not have the same flow rate and velocity information as the NHDPlus data for the U.S. watercourses. In order to estimate the river velocity for the Canadian portion of the Red River, flows and velocities were calculated separately using a similar process as in the NHDPlus data. The contributing drainage area for each stream segment was determined based on the elevation data. An equation was then used to determine flow, as a function of drainage area, based on the NHDPlus data. The flow for the NHN streams was calculated based on these relationships for each flow period. The flow was then used to determine the velocity for each stream segment using the Jobson Method. A major input to this relationship is the stream slope. However, the resolution of the elevation data in Canada was not

adequate to define a unique slope for each stream segment. Instead the overall change in elevation was used to determine an average slope. The result of these calculations was stream velocities that matched well with the NHDPlus data and a seamless stream network for the US and Canadian portions of the Red River.

The stream centerline network was originally extracted for each river from the NHDPlus network to maintain the networking and flow and velocity information found there. The stream centerlines were adjusted to be more accurately aligned using the NHD high-resolution stream centerlines as well as aerial photography. Stream widths were calculated based on the NHD high-resolution stream polygons where available (USGS 2014) using a series of transects along the river centerline. Where not available, stream widths were measured for each stream segment based on aerial photographs. Stream shore types were determined based on aerial photographs and land cover data (see next section). Low and average flow scenarios used the visible shore types, while high flow scenarios assumed the shore type of the surrounding land cover above the stream bank. Lake polygons were derived from the high resolution NHD dataset. The size and shape of some of the lakes were updated for different seasons based on aerial photographs.

River velocity varied between seasons for each hypothetical release site. The mean monthly river velocities for the identified seasons/months are presented in Table 5-6.

Table 5-6 Mean River Velocity Modeled for Each OILMAP Land Release Site and Season

Case #	Release Site	River Flow	Season	Corresponding Month	Average River Velocity (m/s)
1	Mosquito Creek to Lower Rice Lake	Low	Winter	February	0.16
		Average	Summer	July	0.21
		High	Spring	April	1.03
2	Mississippi River at Ball Cub	Low	Winter	March	0.12
		Average	Summer	August	0.31
		High	Spring	April	0.47
3	Sandy River	Low	Winter	March	0.13
		Average	Summer	July	0.24
		High	Spring	April	0.35
4	Shell River to Twin Lakes	Low	Winter	March	0.25
		Average	Summer	August	0.35
		High	Spring	April	0.54
5	Red River	Low	Winter	February	0.31
		Average	Summer	August	0.44
		High	Spring	April	1.02

5.3.2.3 Land Cover Data

The OILMAP Land model uses land cover data to vary the amount of oil that adheres to the land surface as oil moves down slope. The land cover data are used in a gridded format, with each grid cell value representing the type of land cover at that specific location. Land cover code values are then matched to the categories that define oil retention, so that the loss by retention can be accurately calculated as oil flows over the land surface.

The land cover data used was the National Land Cover Database ([NLCD] 2011), created by the Multi-Resolution Land Characteristics Consortium (Homer et al. 2015). The NLCD 2011 is based on a decision-tree classification of 2011 Landsat satellite data with 30-m resolution.

The NLCD 2011 data was transformed to the appropriate coordinate system. The dataset required reclassification of land cover classes to assign them to OILMAP Land values. The classification conversions for the NLCD 2011 data are provided in Table 5-7.

Table 5-7 Mapping Used to Convert the NLCD 2011 Land Cover Categories to OILMAP Land Classification Scheme

NLCD 2011 Code	NLCD 2011 Description	OILMAP Land Code	OILMAP Land Description
11	Open water	5	Water
12	Perennial snow/ice	12	Perennial ice/snow
21	Developed, open space	21	Low intensity residential
22	Developed, low intensity	21	Low intensity residential
23	Developed, medium intensity	22	High intensity residential
24	Developed, high intensity	22	High intensity residential
31	Barren land (rock/sand/clay)	31	Bare rock/sand/clay
41	Deciduous forest	41	Deciduous forest
42	Evergreen forest	42	Evergreen forest
43	Mixed forest	43	Mixed forest
51	Dwarf scrub	51	Shrubland
52	Shrub/scrub	51	Shrubland
71	Grasslands/herbaceous	71	Grasslands/herbaceous
72	Sedge/herbaceous	92	Emergent herbaceous wetlands
73	Lichens	98	Barren land

81	Pasture/hay	81	Pasture/hay
82	Cultivated crops	82	Row crops
90	Woody wetlands	91	Woody wetlands

Table 5-7 Mapping Used to Convert the NLCD 2011 Land Cover Categories to OILMAP Land Classification Scheme

NLCD 2011 Code	NLCD 2011 Description	OILMAP Land Code	OILMAP Land Description
95	Emergent herbaceous wetlands	92	Emergent herbaceous wetlands

For each seasonal scenario, the release was simulated using both Bakken Crude and CLSB/CLWB oil types. Along with the varying chemical and physical properties of the two oil types, other model settings were adjusted for each oil type such as oil retention values for the shore type and the minimum thickness on lake surfaces. The oil retention values used by OILMAP Land for the shore and oil types are provided below (Table 5-8).

Table 5-8 Shoreline Retention Values Applied for Both Oils and Multiple Shore Types

Shore Type	Total Shore Width (m)	Oil Retention Thickness (mm)		Oil Volume Retained (m^3 per km of river)	
		Bakken Crude	Cold Lake Blend	Bakken Crude	Cold Lake Blend
Rock / Concrete	0.5	1	4	0.5	2
Soil	1	2	15	2	15
Sand	2	3	20	6	40
Grass	5	4	25	20	125
Marsh	20	6	40	120	800

Overland trajectory modeling was conducted only for the Mosquito Creek site. The land cover and lake surface oil retention thicknesses used in the model are presented in Table 5-9.

Table 5-9 Land and Lake Surface Retention Values Applied for Both Oils at the Mosquito Creek Site *

Land Cover Type	Oil Retention Thickness (mm)	
	Bakken Crude	Cold Lake Blend
Deciduous Forest	2	13.4
Pasture / Hay	0.6	3.8
Snow [1]	69.6	139.2
Vegetated Lake	0.28	1.68
Lake Surface	0.001	0.1
Under Ice in Lake	1.9	10.6

5.3.2.4 Wind and Temperature Data

Daily climatological statistics consisting of wind speed, wind direction, and air temperature were obtained from the National Oceanic and Atmospheric Administration (NOAA) National Centers for Environmental Information website (NOAA 2016a) and from data provided by Environment and Climate Change Canada's Canadian Climate Normals database (Environment Canada 2016). The preliminary climate datasets consist of three parts:

- Site information: the station location (latitude/longitude) and the month and year of the report
- Daily climatological data
- Monthly averages and totals for the month

The available data for both air temperature and wind speed between 2010 and 2015 (in the U.S.) and 1981 and 2010 (in Canada) were averaged by month. Releases scenarios were simulated under different meteorological conditions (i.e., different wind speed and air temperature for each flow condition/season), which cover the range of weather at the release locations and provide a conservative approach to assessing potential outcomes of a release (i.e., trajectories, fates and effects). Table 5-10 shows the temperatures and wind speeds used for different seasonal scenarios in the model at each release location. Because these were river simulations, salinity was assumed to be zero for all modeling locations.

Table 5-10 Air Temperature (°C and °F) and Wind Speed (m/s) Values Used as Model Inputs for Each OILMAP Land Release Location and Seasonal Scenario

Case #	Release Location	Season / River Flow	Month	Air Temp. (°C)	Air Temp. (°F)	Wind Speed (m/s)
1	Mosquito Creek to Lower Rice Lake	Low	February	-11.50	11.30	4.44
		Average	July	19.25	66.65	3.68
		High	April	4.17	39.51	4.88
2	Mississippi River at Ball Club	Low	March	-3.61	25.50	4.51
		Average	August	18.92	66.06	3.51
		High	April	5.00	41.00	4.88
3	Sandy River	Low	March	-3.07	26.47	4.21
		Average	July	19.96	67.93	3.50
		High	April	5.00	41.0	4.73
4	Shell River to Twin Lakes	Low	March	-4.65	23.63	4.58
		Average	August	18.61	65.50	3.52
		High	April	4.04	39.27	5.05
5	Red River	Low	February	-14.68	5.54	5.19
		Average	August	19.78	67.64	3.98

		High	April	4.02	39.20	5.05

5.3.2.5 Snow Cover Depth

Snow cover depth was considered for only the Mosquito Creek overland scenario. Daily snow depth data are available from the NOAA National Centers for Environmental Information (NOAA 2016b). The data are compiled by NOAA from observations collected by the National Weather Service Cooperative Observer stations and First Order stations. The daily data from January 2006 to December 2014 was acquired and the snow cover depth was averaged for each month at each station. The values for the two closest stations to the Mosquito Creek site were selected and averaged, including Thorhult, Minnesota and the University of Minnesota Itasca Biological Station. The monthly average snow cover depth ranged from 0.0 to 34.8 cm (Table 5-11).

Table 5-11 Monthly Average Daily Snow Cover Depth from 2006–2014

Average Daily Snow Cover Depth (cm)											
Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
29.5	34.8	29.4	14.7	0.6	0.0	0.0	0.0	0.0	1.5	2.5	9.3

During non-winter months, the groundcover is predominantly a grassland/herbaceous cover. However, the area is known for its long cold winters with periods of extensive snow cover. A snow cover of 13.5 in. (34.8 cm) was assumed for the month of February (Table 5-11). The retention of oil in snow was assumed to be 20% for the lighter Bakken Crude, corresponding to a retention depth of 2.7 in. (6.96 cm) and 40% for the heavier CLWB, corresponding to a retention depth of 5.5 in. (13.92 cm) (Allen 2015; Belore and Buist 1988; ACS 2013). While the specific retention of oil by snow will depend upon environmental parameters, the temperature of the released oils, snow cover and type, solar insolation, slope, and other factors, these values align within the expected range from previous studies (Bech and Sveum 1991; Allen 1978; Etkin et al. 2007; Fingas and Hollebone 2015). These studies all indicate that heavier oils with higher viscosities tend to spread less, forming thicker layers in the snow, than lighter oils and diesel fuel.

5.3.2.6 Thickness of Oil Under Ice

Ice coverage is important to consider as it may affect the ultimate trajectory and fate of oil within the winter environment. Ice may reduce the quantity or prevent oil from entering a water

body altogether. Furthermore, it may affect the potential downstream transport and potential for pooling of oil under ice. Fates processes such as evaporation may be affected as well.

Ice cover was considered at each of the modeled locations. During winter conditions, complete coverage (100% ice cover) of the water surface is assumed. If a release were to originate on land (e.g., Mosquito Creek) and travel downslope towards the surface water network, it would be absorbed to some extent by the local snow cover. Any oil that made its way to the watercourse would be prevented or delayed from entering the water body due to the coverage of ice. However, if a release were to occur into the watercourse from the underground/underwater crossing (e.g., all modeled locations other than Mosquito Creek), then all oil would enter into the water column itself. For the purpose of modeling, oil is assumed to rise through the water column and be trapped by the ice cover at the surface. The model assumes that evaporation is prevented completely (0% evaporation) due to the layer of ice on the water surface. The downstream transport of oil is modeled within river sections at the local water velocity; however, oil pools under the ice in lakes. As modeled in the ice-free conditions, complete shoreline oiling occurs in the complete ice cover season as well. However, rather than referring to true shoreline oiling, this term in the winter would more appropriately be named edge-oiling. Shorelines are set to ice-edge and shoreline retention values are lower than those found in non-winter conditions. The retention of oil along the banks during winter seasons refers to the oil that would be trapped below the ice surface along the edge of the river in the narrow region between the ice and the bottom. These conservative approximations maximize the extent of potential oiling.

The equilibrium thickness of oil under ice has been measured in many environments. However, the main focus has been in the marine environment, where thicknesses may range from 1-30 cm (Dickins et al. 2008). Freshwater environments, particularly rivers, are quite different than the open ocean, notably with the level of energy within the environment (e.g., waves and other turbulent processes). Assuming that new ice formed in calm conditions and the underside was flat and smooth, the oil will spread underneath to an equilibrium based upon the balance between surface tension and buoyancy (Barnes et al. 2013). The equilibrium slick thickness may be determined using the equation of Cox et al. (1980):

$$\delta = -8.5(\rho_w - \rho_o) + 1.67$$

Where δ is the thickness of oil under ice in cm and $(\rho_w - \rho_o)$ is the density difference between oil and water. Under the smoothest ice conditions, 5.2–11.5 mm are typical for oils with densities in the range crude oils (Cox et al. 1981). The minimum stable drop thickness for crude oil under ice is approximately 8 mm (Lewis 1976). The equilibrium thickness of CLWB was determined to be 0.4 in. (1.06 cm), while the thickness for Bakken was calculated to be 0.07 in. (0.19 cm). The CLWB is thicker than the aforementioned predictions as it is a heavy crude oil. The Bakken was slightly thicker than the previous values due to the smaller density difference between oil and freshwater, as opposed to saltwater.

5.3.3 SIMAP

5.3.3.1 Geographic and Habitat Data

For geographical reference, SIMAP uses a rectilinear grid to designate the location of the shoreline, the water depth (bathymetry), slope, bottom roughness, and the shore or habitat type. The grid is generated from a digital shoreline or other geographical information using the ESRI Arc/Info compatible Spatial Analyst program. The cells are coded for depth and habitat type; the model then identifies the shoreline using this grid. Thus, in model outputs, the land-water map is only used for visual reference; it is the habitat grid that defines the actual location of the shoreline in the model.

Geographical data including digital shoreline basemap, river geometry, and habitat mapping were obtained from the USGS NHD high-resolution dataset. This includes river polygons that were used to define river area, with slight improvements based upon aerial imagery. Variations in the water area between low/average river flow and high river flow were determined based upon aerial imagery from different seasons. The NHD data followed a high flow condition well. Areas that were regularly dry in summer, fall, or winter were excluded from the river area for the average and low flow conditions. Basemap data were used to define the land/water boundary and habitat data were used to define the types of habitats present within the study area. Habitat grids were used to define the bottom type and vegetation found in watered areas, areas of extensive mud flats and wetlands, and the shore type.

Shore types were characterized based on aerial imagery and photographs posted by Google Earth. For average river flow conditions, the shore type was based upon visible bank type. For low river flow conditions, the shore type was assumed to be ice along natural shorelines and man-made structures (e.g., ditches) where present. For high river flow conditions, the shore types were assigned based upon the land cover data above the riverbank, except for man-made structures. The bottom type was defined as silt and mud with some regions characterized as wetlands from imagery and mapping that identified wetlands.

River depth was characterized based on flood insurance studies for Palisade and Aitkin County (FEMA 1983, 1996) and the St Paul District Corps of Engineers (1980). Depths were provided at various distances from known locations along the river. These locations were mapped and assigned their corresponding depth. Depths were linearly interpolated along the river centerline between these known values. Lacking any cross sectional river profiles, a rectangular river channel was assumed. To create a rectangular shaped depth profile (i.e., constant depth from bank to bank at any cross section in the river), a grid was created based upon these centerline depths.

River depth and habitat are presented for the Mississippi River at Palisade and Little Falls in Figure 5-30 through Figure 5-37 for each of the modeled seasons.

5.3.3.2 Environmental Data

5.3.3.2.1 River Currents

Currents have an important influence on the trajectory and fate of the oil, and are critical data inputs. The SIMAP modeling system used spatially varying current fields throughout a gridded domain of the river within the study area to force oil throughout the domain. The current fields were generated using BFHYDRO, a hydrodynamic model created by RPS ASA. The model was used to first generate a boundary fitted grid mapped to the wetted domain, as defined by the NHD. It was then used to generate a spatially varying current field for three different environmental conditions representing low, average, and high monthly average river flows and associated current speeds.

5.3.3.2.1.1 Hydrologic Analysis

NHDPlus is a geo-spatial, hydrologic framework dataset built by the US EPA Office of Water, assisted by the USGS. The NHDPlus data set was queried to determine the variability in monthly flows and river reach speeds within the study area. NHDPlus includes an estimated monthly and annual average stream flow rate and velocity for each stream segment. Flow is estimated using EROM. This method determines river flow based on estimates of accumulated runoff based on the elevation data, evaporative loss, and various adjustments based on gages within the region. The velocities are calculated based on the estimated flow using the Jobson Method (Jobson 1996). A summary of the monthly flows and current speeds at points within the Palisade and Little Falls domains are presented in Table 5-12. Based on analysis of this data, it was determined that the months representing low river flow conditions were March for the Mississippi River at Palisade and February for the Mississippi River at Little Falls. Average river flow conditions occurred in July, with high river flow conditions in April for both locations.

Table 5-12 Summary of Monthly River Flows and Current Speeds for SIMAP Release Sites

Month	Mississippi River at Palisade		Mississippi River at Little Falls	
	Flow (m^3/s)	Current Speed (m/s)	Flow (m^3/s)	Current Speed (m/s)
January	53.8	0.35	99.5	0.47
February	52.9	0.35	95.2	0.46
March	45.6	0.33	142.1	0.54
April	109.6	0.47	276.8	0.74
May	92.2	0.44	252.3	0.70
June	72.5	0.40	167.1	0.58
July	66.1	0.38	178.2	0.60
August	50.6	0.34	113.4	0.49
September	48.2	0.34	109.0	0.48

Table 5-12 Summary of Monthly River Flows and Current Speeds for SIMAP Release Sites

Month	Mississippi River at Palisade		Mississippi River at Little Falls	
	Flow (m^3/s)	Current Speed (m/s)	Flow (m^3/s)	Current Speed (m/s)
October	79.5	0.41	138.7	0.54
November	85.2	0.42	142.0	0.54
December	63.0	0.37	117.5	0.50
Low	45.6	0.33	95.2	0.46
Average	68.3	0.38	152.7	0.55
High	109.6	0.47	276.8	0.74

5.3.3.2.1.2 Hydrodynamic Modeling System

The hydrodynamic modeling was carried out using the in-house modeling tool BFHYDRO within the Water Quality Mapping and Analysis Program (WQMAP) modeling system, both of which were created by RPS ASA (Mendelsohn et al. 1995). WQMAP integrates geographic information (land use, watersheds, etc.), environmental data (water quality parameters, surface elevations and velocities, stream flows, bathymetry, etc.), and models (analytical and numerical, hydrodynamic, pollutant transport, etc.). The WQMAP computational engine is a family of general curvilinear coordinate system computer models including a boundary conforming gridding model (BFGRID) and a hydrodynamic model (BFHYDRO). This study used BFGRID to generate a grid of the model domain and BFHYDRO to perform simulations to generate current fields.

The boundary fitted grid generation model BFGRID is a tool used to build a grid of the study area on which the hydrodynamics and pollutant transport models run. The boundary-fitted coordinate system approach generates transformation functions such that all domain boundaries are coincident with coordinate lines. The grid generation is accomplished by using a set of coupled quasi-linear elliptic transformation equations to map an arbitrary horizontal multi-connected region from physical space to a rectangular mesh structure in the transformed horizontal plane (Mendelsohn et al. 1995; Spaulding 1984; Thompson et al. 1977). While the transformed set of equations is considerably more complex than the original set, the transformed boundary conditions are specified on straight lines and the coordinate spacing is uniform in the transformed plane. It should further be noted that the orthogonal and conformal curvilinear grids, as well as the simple stretched rectangular and square grids, are special cases of the general curvilinear, boundary-fitted coordinate approach used here.

Key boundary points are specified by the user and the structure of computational grid (I,J coordinates) is defined interactively on a map using a graphical user interface. After specifying key grid nodes (grid corners) along the domain boundary, the model interpolates the remaining

boundary node locations and then solves the transformed equations to locate the interior nodes. The resulting non-orthogonal grid contains quadrilaterals of various sizes and orientation to both resolve fine detail where needed, and cover large areas with coarse resolution where resolution is not required. The hydrodynamic and water quality models then use this grid in their numerical solution of the appropriate conservation equations.

BFHYDRO is a three dimensional, general curvilinear coordinate, boundary-fitted computer model (Mendelsohn 1998; Muin and Spaulding 1997; Huang and Spaulding 1995; Muin 1993) and is used to predict elevations, and current velocities within the gridded domain. The boundary-fitted model matches the model coordinates with the shoreline boundaries of the water body, accurately representing the study area. This system also allows the user to adjust the model grid resolution as desired. This approach is consistent with the variable geometry of the riverine shoreline. The model may be applied in either two or three dimensions, depending on the nature of the inquiry and its complexity. The hydrodynamic model uses the boundary fitted method and grid system as described above. The three dimensional conservation of mass and momentum equations, with approximations suitable for lakes, rivers, and estuaries (Swanson 1986; Muin 1993) that form the basis of the model, are then solved in this transformed space. In addition, a sigma stretching system is used in the vertical dimension to map the free surface and bottom onto coordinate surfaces to resolve variable surface elevations and bathymetric variations. The resulting equations are solved using an efficient semi-implicit finite difference algorithm for the exterior mode (two dimensional vertically averaged), and by an explicit finite difference leveled algorithm for the vertical structure of the interior mode (three dimensional) (Swanson 1986). The velocities are represented in their contra-variant form.

The basic equations are written in spherical coordinates to allow for accurate representation of large modeled areas. The conservation equations for water mass and momentum (in three dimensions) form the basis of the model, and are well established. It is assumed that the flow is incompressible, that the fluid is in hydrostatic balance, the horizontal friction is not significant, and the Boussinesq approximation applies all customary assumptions.

The boundary conditions are as follows:

- At land, the normal component of velocity is zero
- At open boundaries, the free surface elevation must be specified, and temperature (and salinity for estuarine and coastal applications) specified on inflow
- A bottom stress or a no slip condition is applied at the bottom. No temperature (heat) is assumed to transfer to or from the bottom, a conservative assumption as some transfer of heat to the bottom is expected to occur.
- A wind stress and appropriate heat transfer terms are applied at the surface

The set of governing equations with dependent and independent variables transformed from spherical to curvilinear coordinates, in concert with the boundary conditions, is solved by a semi-implicit, split mode finite difference procedure (Swanson 1986). The equations of motion are vertically integrated and, through simple algebraic manipulation, are recast in terms of a single

Helmholtz equation in surface elevation. This equation is solved using a sparse matrix solution technique to predict the spatial distribution of surface elevation for each grid.

The vertically averaged velocity is then determined explicitly using the momentum equation. This step constitutes the external or vertically averaged mode. Deviations of the velocity field from this vertically averaged value are then calculated, using a tridiagonal matrix technique. The deviations are added to the vertically averaged values to obtain the vertical profile of velocity at each grid cell, thereby generating the complete current patterns. This constitutes the internal mode. The methodology allows time steps based on the advective, rather than the gravity, wave speed (as in conventional explicit finite difference methods) and, therefore, results in a computationally efficient solution procedure (Swanson 1986; Muin 1993).

5.3.3.2.1.3 Hydrodynamic Solution

Hydrodynamic modeling was performed to generate river current speeds that matched the average reach speeds in the NHDPlus data set for the designated months. The BFHYDRO model was used to generate current fields that matched the NHDPlus average reach estimates. The NHDPlus estimates are simplifications that assign constant current speeds for a reach. In reality, there are variations across and along each reach due to bottom elevation changes, river cross-section changes, and other local features. The BFHYDRO model was used to simulate this variability, while representing the NHDPlus average reach speed. A summary of the range of river current speeds (10th, 50th and 90th percentile) for each representative season for both the Mississippi River at Palisade and the Mississippi River at Little Falls domains are summarized in Table 5-13. Illustrations of the spatial variability of current speeds location for low, average and high flow seasons are presented in Figure 5-38 through Figure 5-40 for the Mississippi River at Palisade release location and in Figure 5-41 through Figure 5-43 for the Mississippi River at Little Falls release, respectively.

Table 5-13 Mean River Velocity Modeled for Each SIMAP Release Site and Season

Case #	Release Site	Season / River Flow	Month	River Velocity (m/s)
6	Mississippi River at Palisade	Low	March	0.33
		Average	July	0.38
		High	April	0.47
7	Mississippi River at Little Falls	Low	February	0.46
		Average	July	0.60
		High	April	0.74

5.3.3.2.2 Wind and Temperature

The same wind and temperature data sources for that were used as inputs for the OILMAP Land scenarios (Section 5.3.2.4) were also used to develop wind and temperature information for the two Mississippi River SIMAP scenarios. Daily climatological statistics from 2000 to 2015 consisting of wind speed, wind direction, and air temperature were obtained from the NOAA National Centers for Environmental Information website (NOAA 2016a) and were averaged by month. Table 5-14 depicts the temperatures and wind speeds used for each seasonal scenario at each release location. Because these were river simulations, salinity was assumed to be zero for all modeling locations.

Table 5-14 Air Temperature and Wind Speed Values Used as Model Inputs for Each SIMAP Release Location and Seasonal Scenario

Case #	Release Location	Season / River Flow	Month	Air Temp. (°C)	Air Temp. (°F)	Wind Speed (m/s)
6	Mississippi River at Palisade	Low	March	-3.19	26.26	4.78
		Average	July	20.19	68.34	3.95
		High	April	5.03	41.05	5.24
7	Mississippi River at Little Falls	Low	February	-8.33	17.01	4.30
		Average	July	22.06	71.71	3.47
		High	April	7.06	44.71	4.85

Winds may physically transport oil on the water surface and wind speed and direction at the water surface may make a difference between limited (especially in windy sections of river) or extensive transport. The wind data available is for open areas at some distance from the release sites examined, as opposed to in the forested stream areas modeled; thus, local winds at each point downstream from the release location may be different than the reported wind speed and direction. Because of these uncertainties and the expected variability in direction, the SIMAP model conservatively assumed wind drift transport as zero (i.e., winds did not laterally transport oil or push it ashore) for each of the modeling locations. The modeled wind was therefore not a true vector as it had magnitude, but no direction. Because of this assumption, winds may add to the evaporation of surface oil in the model output, and could enhance the vertical mixing of the surface water, in some instances keeping subsurface oil entrained or entraining more oil under higher wind speeds.

5.3.3.2.3 Total Suspended Solids

The amount of sediment transport can change by several orders of magnitude based on location and flow conditions, with extensive of sediment transport during high river flow conditions (especially storm events), and very low sediment transport and clear water during low river flow conditions (e.g., under winter ice cover). During peak storm events, it is not uncommon to have values exceeding 1,000 mg/L in some locations. Oil droplets may stick to suspended

sediments and settle out to the bottom. The sedimentation rate was set to 1 mm/day for high flow scenarios and 0.1 mm/day for low flow scenarios. At suspended sediment concentration of about 100 mg/L, sedimentation of oil and PAHs becomes substantial. Sediment loads were assumed to be 99, 25, and 10 mg/l for the high, average, and low river flow conditions, respectively.

5.3.3.2.4 Ice Cover

Oil interactions with mobile and immobile ice involve several processes that affect the transport and fate of the oil. Oil released under water may become trapped under the ice in ridges and keels, or build up along and become trapped (Drozdowski et al. 2011). Many of these interactions and processes are at a finer scale than can be captured in oil spill models using inputs from the available large scale meteorological, hydrodynamic and coupled hydrodynamic-ice models. SIMAP simulates the influence of ice on net transport and fate processes by considering potential reduction in the surface area of the oil and the water in contact with the atmosphere, which changes the effects of the wave environment, spreading, movements, dissolution, volatilization, and mixing on the released oil.

In SIMAP, when oil encounters ice at the surface of the river, it is assumed to trap along the ice edge and remain immobile until ice retreats. In areas deep enough for ice to have subsurface open channels (i.e., where the ice sheet may not extend completely to the riverbed in all areas), SIMAP allows entrained oil to circulate underneath the surface ice using subsurface current data for transport. The 100% ice coverage on the rivers during the winter was assumed to have a thickness of ice of 0.5 m. Therefore, subsurface oil spillets continued to move downstream with currents, until the spillets reached the water-ice interface, at which point they "stick."

The presence of ice can shelter oil from the wind and waves (Drozdowski et al. 2011). Thus, weathering processes such as evaporation and emulsification, and behaviors such as spreading and entrainment are slowed (Spaulding 1988). Field data show evaporation, dispersion, and emulsification s slowed substantially in ice leads, contrary to some laboratory experiments. Wave-damping, the limitations on spreading dictated by the presence of sea ice, and temperature appear to be the primary factors governing observed spreading and weathering rates (Sørstrøm et al. 2010).

During the low flow river conditions, corresponding with the winter months, ice cover was assumed to be 100%. With 100% ice coverage, SIMAP stops the processes of evaporation, emulsification, entrainment, volatilization, and spreading.

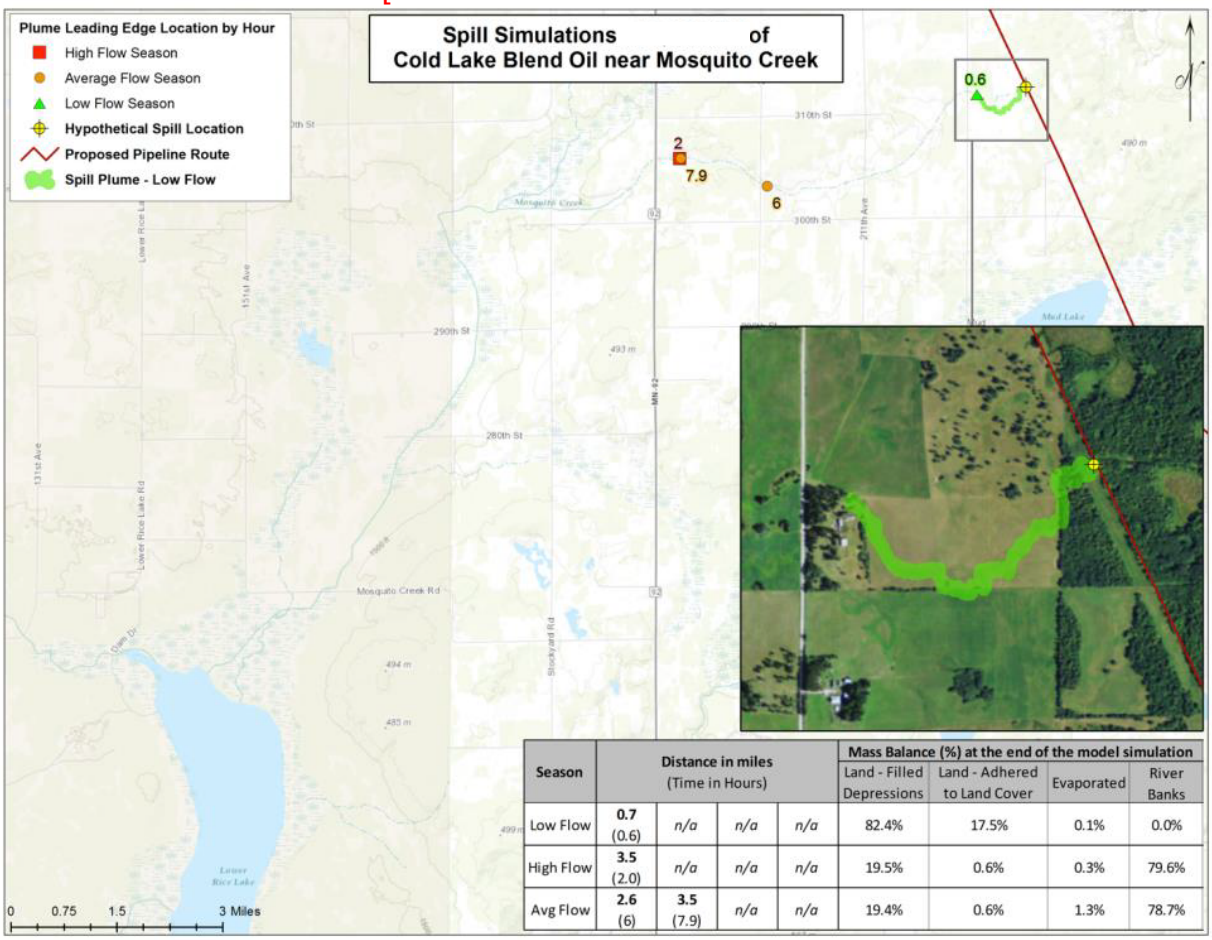
6.0 TRAJECTORY AND FATE RESULTS FOR MODELING LOCATIONS

6.1 DESCRIPTION OF OILMAP LAND MODEL OUTPUTS

This section provides modeled predictions of expected downstream transport and mass balance information for CLB (either Winter or Summer) and Bakken Crude oil under high, average, and low river flow conditions at five hypothetical release locations modeled in OILMAP Land.

As described in Section 5.1.1, OILMAP Land predicts the trajectory and fate of released oil. The model includes a land component that predicts how much oil will adhere to vegetation and soils and remain in depressions in the landscape, as well as the quantity that would be lost to evaporation during overland flow. Overland trajectory and fate were modeled only for the Mosquito Creek site (Section 6.2), as the other four sites assumed that oil was released directly into a watercourse. OILMAP Land also predicts the downstream trajectory and fate of released oil in water. The model calculates the amount of released oil that would evaporate, adhere to the shoreline, and remain on the water surface. In an actual oil release, other processes such as dissolution and dispersion would come into play (Section 7.1.2).

Figures are provided for each of the five modeling locations and two oil types in Sections 6.1.1 through 6.1.5. Each figure includes each of the three modeled seasons that correspond with high, average, and low river flow. In these figures, symbols with different color/shape combinations denote the location and time in hours of the farthest downstream movement of released crude oil for each set of scenarios at a given location. The mass balances are also provided, summarizing how much of the oil remained on the river surface, evaporated to the atmosphere, or stranded on the riverbanks. The model was run for 24 hours, or until no further oil remained on the river surface (i.e., all oil had evaporated or adhered to shorelines). If there was oil on the river surface after 24-hours, it would continue downstream, further oiling shorelines, until it either evaporated and stranded, or was captured by emergency response operations.



6.1.1 Unmitigated Hypothetical Release Case 1—Mosquito Creek to Lower Rice Lake

Mosquito Creek is a small stream located approximately 6 miles (9.7 km) south of Bagley, Minnesota. The pipeline does not actually cross Mosquito Creek; however, the simulated release location is located approximately 2,000 ft (610 m) to the northeast from the head of the creek and at a higher elevation. Based on local topography, oil would need to travel overland approximately 3,300 ft (1,006 m) before entering Mosquito Creek. Mosquito Creek flows to the southwest for approximately 12 miles (19.3 km) before entering Lower Rice Lake. Mosquito Creek is the smallest stream of the sites investigated with an average width of approximately 15 ft (5 m). At the widest points around its entrance into Lower Rice Lake, it is approximately 30 ft

(10 m) across, while the upper portions of the creek are much less ranging from approximately 3–15 ft (1–5 m) wide. Expected environmental and river flow conditions throughout the year for Mosquito Creek are provided in Table 5-6. In all release scenarios, spills were not predicted to enter Lower Rice Lake before all of the oil had either evaporated or adhered to the land cover or stream shorelines. Maps of the predicted downstream trajectory and mass balance tables of CLB (Figure 6-1) and Bakken Crude (Figure 6-2) seasonal scenarios for the Mosquito Creek release site are provided at the beginning of the following subsections.

6.1.1.1 Cold Lake Blend Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Season	Distance in miles (Time in Hours)				Mass Balance (%) at the end of the model simulation			
					Land - Filled Depressions	Land - Adhered to Land Cover	Evaporated	River Banks
Low Flow	0.7 (0.6)	n/a	n/a	n/a	82.4%	17.5%	0.1%	0.0%
High Flow	3.5 (2.0)	n/a	n/a	n/a	19.5%	0.6%	0.3%	79.6%

...NONPUBLIC DATA HAS BEEN EXCISED]

Figure 6-1 Predicted Downstream Transport of CLB Oil Near Mosquito Creek

6.1.1.1.1 Trajectory and Fate Results for High River Flow (Spring)

Flow rates on Mosquito Creek during the spring season (April) resulted in peak average river velocities ranging from 1.67 to 2.30 miles per hour (mph) (0.75 to 1.03 m/s). Under high river flow, CLSB was predicted to travel approximately 3.5 miles (5.6 km) downstream. After 2.0 hours, approximately 0.3% of the CLSB evaporated to the atmosphere, 20.1% filled depressions on land or adhered to land cover, and the remaining 79.6% oiled shorelines. Note that the model predicts that no CLSB would remain on the water surface after 2.0 hours since all of the released oil would have been retained in depressions, adhered to land cover, or evaporated by that point in time.

6.1.1.1.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

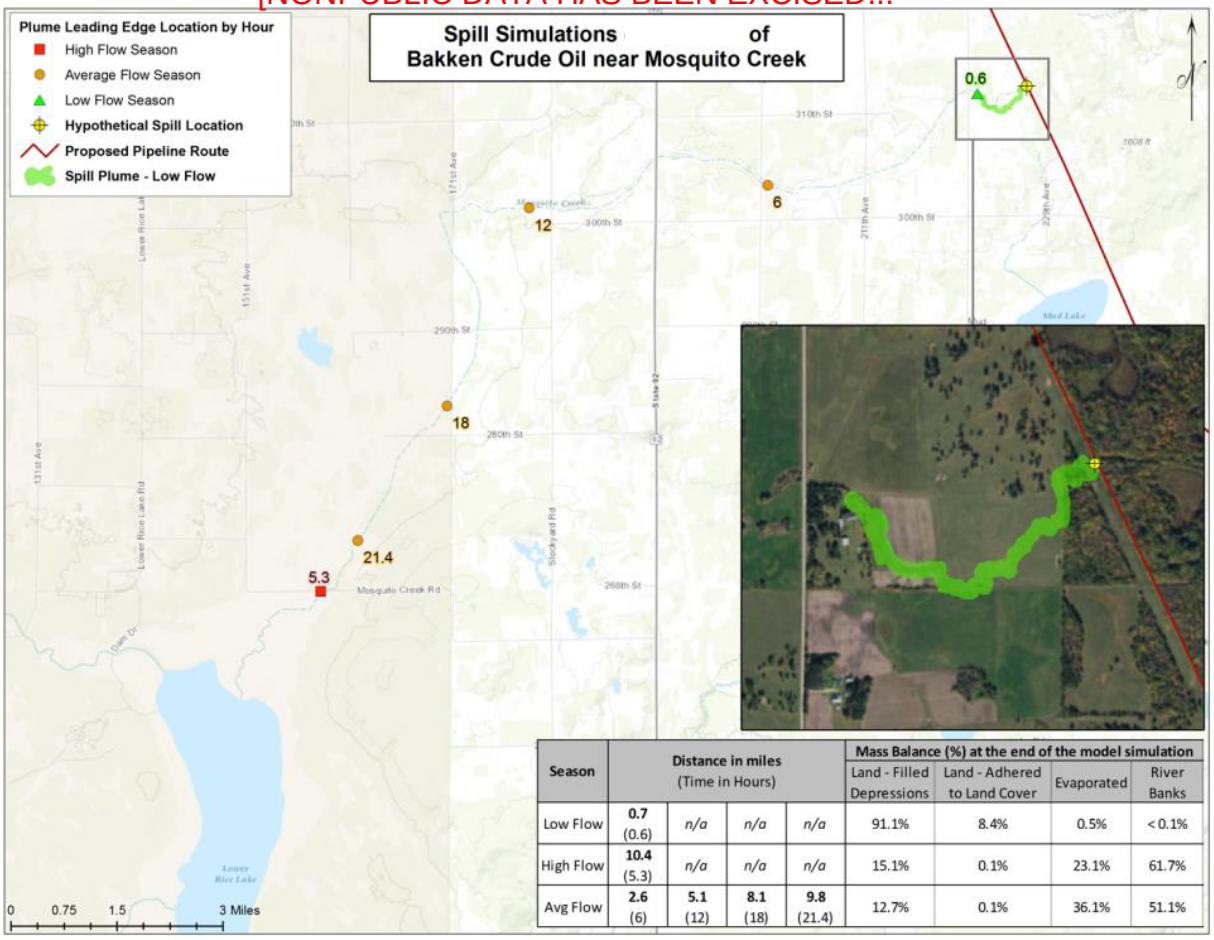
Flow rates on Mosquito Creek during the summer (July) and fall resulted in average river velocities ranging between 0.43 to 0.47 mph (0.19 and 0.21 m/s). These velocities were significantly slower than the high river flow conditions during the spring. As in the high flow condition, all of the released CLSB was predicted to adhere to the land cover, adhere to the shorelines, or evaporate to the atmosphere within the same 3.5 miles from the release site. However, under average river flow conditions with lower velocities, it took approximately 7.9 hours to reach that same distance. After 7.9 hours, approximately 1.3% of the CLSB evaporated to the atmosphere, 20.0% filled depressions on land or adhered to land cover, and the remaining 78.7% oiled shorelines. Note that the model predicted that there would be no CLSB on the water surface after 7.9 hours.

Under the average river flow condition (i.e., summer), more of the CLSB was predicted to evaporate, when compared to the high flow conditions (i.e., spring). This is partially due to the higher temperatures in this summer scenario, however, the main factor in the increased evaporation was the longer time required for the CLSB to move downstream due to the slower stream velocities. The longer time allowed for more complete evaporation of the CLSB.

6.1.1.1.3 Trajectory and Fate Results for Low River Flow (Winter)

Under winter (February) conditions, the region near the Mosquito Creek release location was assumed to be covered in snow at a depth of 34.8 cm. In addition, it was assumed that Mosquito Creek would be frozen over (100% coverage of ice), with a layer of snow on top. Therefore, a release of CLWB from the pipeline onto land would result in a spill traveling over the snow surface and onto Mosquito Creek, but the oil would not enter the water.

Under winter conditions, CLWB was predicted to travel approximately 0.7 miles (1.13 km) over the land surface. Approximately 82.4% of the CLWB filled depressions in the land surface, 17.5% adhered to the land cover, and only 0.1% evaporated. After 0.6 hours, all of the released CLWB evaporated, adhered to the land cover, or filled depressions in the land surface; therefore, the model simulation stopped at that time.



Considerably more CLWB was predicted to adhere to the land cover in winter conditions due to the holding capacity of the snow cover, which is over 35 times greater than that of the typical

land cover in this area for CLWB (Table 5-9). With Mosquito Creek frozen over, additional depressions were created in surface of the stream that allowed more CLWB to form pools on the ice surface.

Very little evaporation was predicted to occur under winter conditions due to the very short (0.6 hour) duration of the simulation. Lower air temperatures also slow evaporation. Additionally, a reduced surface area for exchange was predicted due to less spreading of oil and no downstream transport. This resulted in a smaller surface area over which evaporation could occur.

6.1.1.1 Bakken Crude Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Season	Distance in miles (Time in Hours)				Mass Balance (%) at the end of the model simulation			
					Land - Filled Depressions	Land - Adhered to Land Cover	Evaporated	River Banks
Low Flow	0.7 (0.6)	n/a	n/a	n/a	91.1%	8.4%	0.5%	< 0.1%

Avg Flow	2.6 (6)	5.1 (12)	8.1 (18)	9.8 (21.4)	12.7%	0.1%	36.1%	51.1%

...NONPUBLIC DATA HAS BEEN EXCISED]

Figure 6-2 Predicted Downstream Transport of Bakken Crude Oil Near Mosquito Creek

6.1.1.1.4 Trajectory and Fate Results for High Flow (Spring)

Under high river flow conditions (April), Bakken crude traveled approximately 10.4 miles (16.7 km) downstream. After 5.3 hours, approximately 23.1% of the Bakken crude had evaporated to the atmosphere, 15.2% filled depressions on land or adhered to land cover, and the remaining 61.7% oiled shorelines. Note that there was no Bakken crude remaining on the water surface after 5.3 hours, as the model predicted that all of the oil would have been lost from the water surface by that point.

Under high river flow conditions, the Bakken crude resulted in oiling of shorelines nearly 3 times farther downstream (10.4 miles) than the CLSB (3.5 miles). The difference in the extent of downstream transport was primarily due to differences in the shoreline oil retention between the two oils. Because of its higher viscosity and other parameters, CLSB stranded upon shorelines more thickly than Bakken Crude oil, resulting in larger amounts of CLSB along the same length of shoreline. In contrast, the same amount of Bakken Crude oiled longer lengths of shoreline with a reduced thickness. While this result is logical, it is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point was oiled to its maximum holding capacity) as oil made its way downstream. In the event of an actual release, the downstream extents of CLSB and Bakken Crude may be more similar, and the effects of CLSB may extend farther downstream than presented, with patchy coverage.

Due to its lighter nature and higher volatile content, Bakken Crude was predicted to evaporate more completely (23.1%) than the CLSB (0.3%) oil. The Bakken Crude oiled farther downstream, which also took more time. The additional time for downstream transport allowed for more time over which the oil evaporated to the atmosphere.

6.1.1.1.5 Trajectory and Fate Results for Average Flow (Summer-Fall)

Under average river flow conditions (July), the Bakken Crude traveled approximately 9.8 miles downstream. At that point, approximately 36.1% of the Bakken Crude had evaporated to the atmosphere, 12.7% filled depressions on land or adhered to land cover, and the remaining 51.1% would have adhered to shorelines. The model predicted that no Bakken Crude would remain on the water surface after 21.4 hours.

Under average flow conditions, the Bakken Crude was predicted to oil 0.6 fewer miles (0.97 km) of shoreline than during high river flow conditions. Under average river flow conditions, the Bakken Crude was transported downstream at a slower velocity than that of the high river flow conditions. Since this allowed more time for evaporation from the stream surface, less oil was available for shoreline retention. Although the land surface retained the same volume of oil under high flow and average flow conditions, more of the released oil evaporated over the 21.4 hours of the average flow simulation, than during the 5.3 hour high flow simulation. This resulted in less oil remaining on the land surface at the end of the simulation.

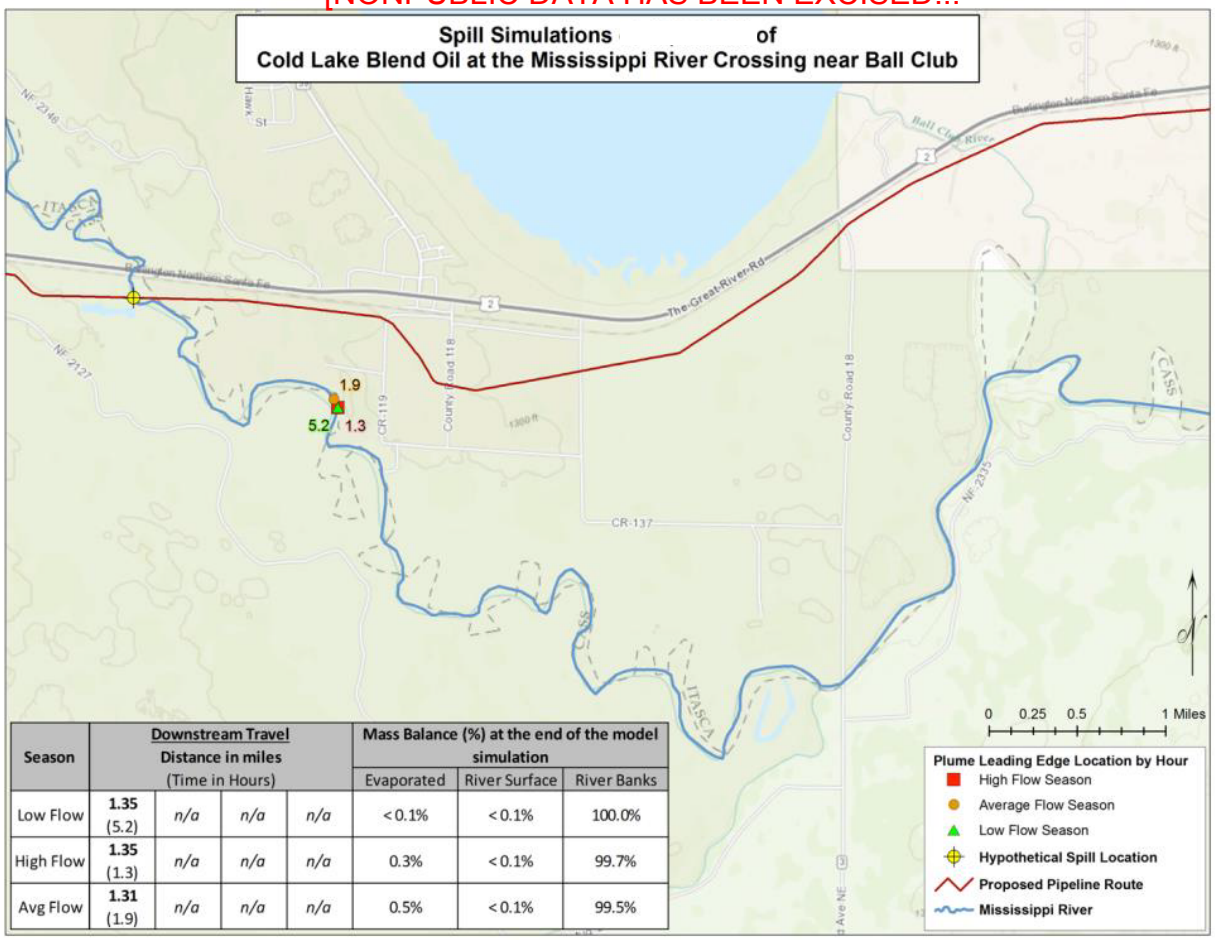
6.1.1.1.6 Trajectory and Fate Results for Low Flow (Winter)

Under winter conditions (February) Bakken crude traveled approximately 0.7 miles over the land surface. At that point, approximately 91.1% of the oil filled depressions in the land surface, 8.4% adhered to the land cover, and only 0.5% evaporated. After 0.6 hours, all of the released Bakken Crude evaporated, adhered to the land cover, or filled depressions in the land surface; therefore, the model simulation stopped.

Considerably more Bakken Crude adhered to the land cover during low flow (winter) conditions than during high or average river flow conditions, due to the holding capacity of snow cover. The holding capacity of snow for Bakken Crude was over 100 times the retention values of the typical land cover in this area (Table 5-9). However, the holding capacity on snow for Bakken Crude is about half of that for CLWB; therefore, a release of Bakken will create a footprint that is nearly double the areal extent of CLWB. The model predicts that very little evaporation will occur over the 0.6 hours of the simulation under winter conditions, since lower air temperatures slowed evaporative losses. Additionally, the smaller surface area, due to reduced spreading of either type of oil without entering the creek, resulted in a smaller surface area for evaporation.

6.1.2 Unmitigated Hypothetical Release Case 2—Mississippi River at Ball Club

The Mississippi River passes to the south and west of the town of Ball Club, Minnesota. The pipeline route crosses the Mississippi River 1.25 miles (2.01 km) to the west of Ball Club, and 400 ft (122 m) south of U.S. Highway 2. At this location the Mississippi River flows to the east through an extensively marshy area. Approximately 12.2 miles (19.6 km) downstream, the river passes through the southern end of White Oak Lake, and then turns to the south. Under low or average river flow conditions the main channel of the Mississippi River passes to the south of White Oak Lake, with only small marshy streams connecting them. Under high river flow conditions, hydraulic connections are present between the river and lake; therefore, it was assumed that under high river flow conditions that the main pathway of the Mississippi River could transport oil into White Oak Lake. The width of the Mississippi River averages approximately 160 ft (48.8 m) in this area. Expected environmental and flow conditions throughout the year for Mississippi River near Ball Club are provided in Table 5-6.



The shore type for the majority of the Mississippi River in this region is marsh. An initial set of scenarios was run using this marsh shore type. However, the high retention value for marsh shore types (120 m^3/km of river for Bakken crude and 800 m^3 for CLB (Table 5-8) resulted in minimal transport of oil down the Mississippi River. Due to the uncertainty of how much oil would be able to infiltrate the marshy shoreline, based on the water level, a second set of scenarios were run assuming that the marsh shoreline was instead grass, with a lower oil retention capacity. Both sets of results are presented. It is anticipated that if an actual release were to occur that downstream oil transport may be somewhere between the two predicted downstream distances.

Trajectory and Fate Results for Modeling Locations
January 13, 2017

The predicted downstream trajectory and mass balance tables for CLB (Figure 6-3) and Bakken Crude (Figure 6-5) seasonal scenarios for the Mississippi River near Ball Club release site with marsh shore type are provided. Results for an assumed grass shore type for CLB (Figure 6-4) and Bakken Crude (Figure 6-6) are also provided.

Figure 6-4 Predicted Downstream Transport of CLB oil at the Mississippi River at Ball Club Release Location With Assumed Grass Shoreline

6.1.2.1.1 Trajectory and Fate Results for High Flow (Spring)

Flow rates for the Mississippi River during the spring (April) resulted in peak average river velocities during April. Velocities ranged between 0.34 to 1.25 mph (0.15 and 0.56 m/s) for the portion of the river modeled in the marsh shoreline scenario runs and between 0.27 and 1.28 mph (0.12 and 0.57 m/s) for the longer portion of river modeled in the grass shoreline runs. The OILMAP Land model transported oil downstream with these velocities to a point where all oil had evaporated and/or adhered to the shoreline.

Under high river flow for marsh shorelines, CLSB was predicted to travel a total of approximately 1.35 miles (2.17 km) downstream, within 1.3 hours of the release. At this time, the model predicts that no CLSB would remain on the water surface. Approximately 99.7% of the CLSB was

predicted to oil the shorelines of the Mississippi River, and 0.3% would have evaporated into the atmosphere.

Under high river flow conditions with grass shorelines, CLSB was predicted to travel a total of approximately 8.1 miles (13.0 km) downstream, within 8.0 hours of the release. At this time, the model predicted that all of the oil would have been lost from the water surface. Approximately 95.2% of the CLSB was predicted to oil shorelines of the Mississippi River, and 4.8% would have evaporated into the atmosphere.

6.1.2.1.2 Trajectory and Fate Results for Average Flow (Summer-Fall)

Average flow rates for Mississippi River occurred during the summer (August) with river velocities ranging between 0.27 to 0.72 mph (0.12 and 0.32 m/s) for the portion of river modeled in the marsh runs and between 0.22 and 0.72 mph (0.10 and 0.32 m/s) for the longer portion of river modeled in the grass shoreline runs. These river velocities were approximately 58–67% of those that would occur under the modeled high flow conditions.

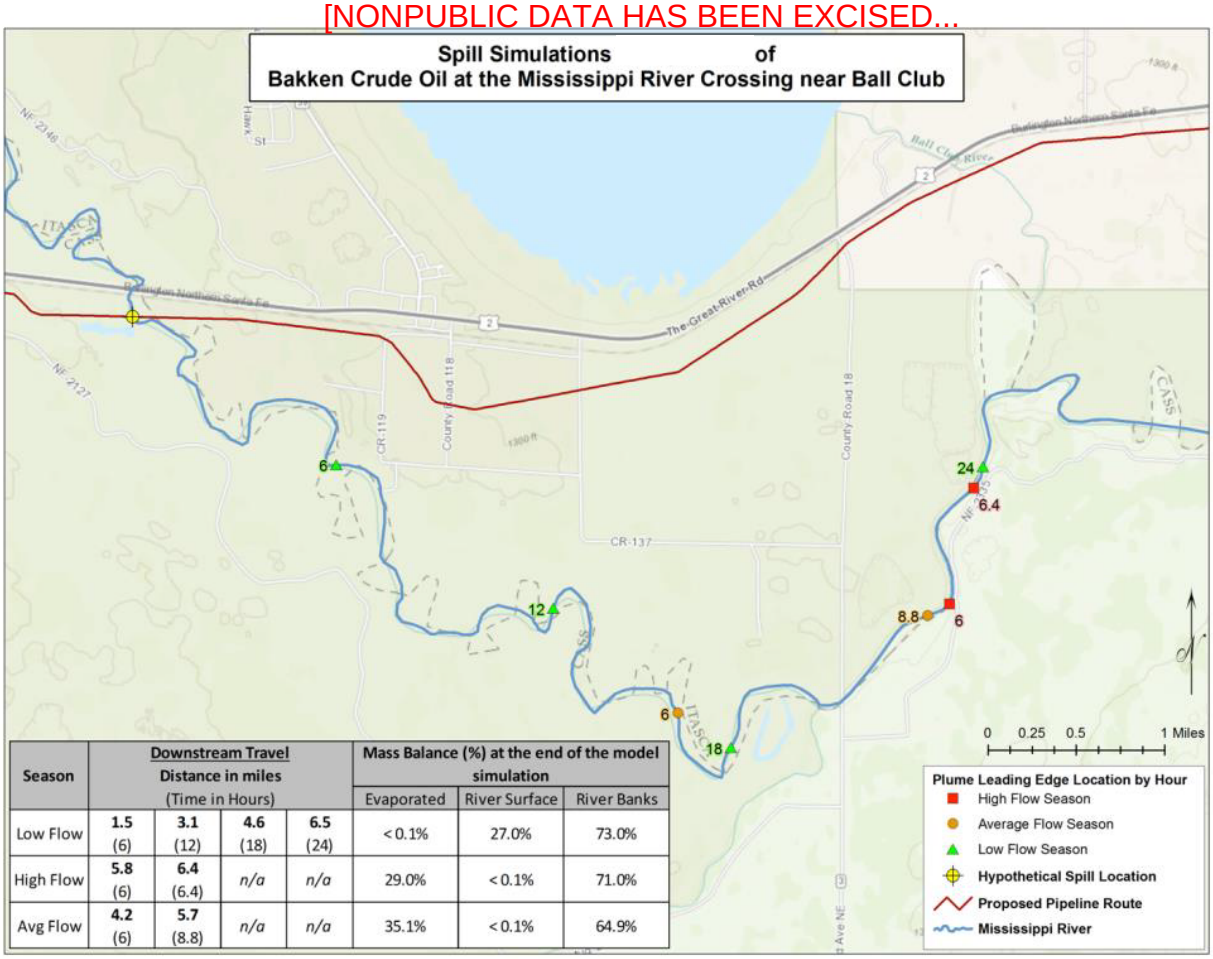
Similar to the high river flow conditions with marsh shorelines, CLSB was predicted to travel a total of approximately 1.31 miles (2.11 km) downstream, under average river flow. However, under average river flow conditions, it would take approximately 1.9 hours to reach this same distance due to the lower stream velocities. At this time, there would be no remaining CLSB on the river surface; approximately 99.5% of the CLSB was predicted to be on the shorelines, while the remainder (0.5%) would have evaporated into the atmosphere.

Under average river flow with grass shorelines, CLSB was predicted to travel a total of approximately 8.0 miles (12.9 km) downstream. However, with lower stream velocities, it took approximately 12.0 hours to reach this distance. At this time the model predicted that there would be no CLSB on the river surface; approximately 93.7% of the CLSB would have adhered to the shorelines of the Mississippi River, and 6.3% would have evaporated into the atmosphere.

Relative to the high river flow condition, more of the CLSB was predicted to evaporate. This is mainly due to the longer time required for the CLSB to move down stream, due to the lower stream velocities. In addition, the higher temperatures during the summer conditions results in more evaporation. The slight reduction in oil remaining on the river shoreline in the average river flow condition was the result of this increase in evaporation.

6.1.2.1.3 Trajectory and Fate Results for Low Flow (Winter)

Under winter conditions (March), it was assumed that Mississippi River would be frozen over completely (100% coverage of ice). It was also assumed that CLWB would be released directly into the river from the pipeline, which is located under the riverbed. Oil released into the water would remain in the water or be trapped under the ice. The ice cover would prevent any evaporation to the atmosphere. Flow rates for the Mississippi River during these winter conditions resulted in minimum river velocities during March, which ranged between 0.22 to 0.34 mph (0.10 and 0.15 m/s). These river velocities were approximately 30% of the high river flow conditions.



Under low river flow conditions with marsh shorelines, CLWB was predicted to travel a total of approximately 1.35 miles (2.17 km) downstream. However, under low river flow conditions with the lowest stream velocities, it took approximately 5.2 hours to reach this same distance. At this time there was no CLWB on the river surface, as the model predicts that all of the CLWB (100%) would have adhered to the shoreline. In an actual spill, the released oil would collect in pockets under the ice, as well as dissolve and disperse in the water column. Some released oil might also collect in openings in the ice where a small portion of the oil would evaporate.

Under low river flow with grass shorelines, CLWB was predicted to travel a total of approximately 6.5 miles (10.5 km) downstream, over the full 24-hour modeled period. Approximately 76.0% of the CLWB was predicted to adhere to the shorelines of the Mississippi River, and the remaining 24.0% would remain in the river, below the ice, at the end of the 24 hour simulation. If left unmitigated, it is expected that the remaining CLWB would continue downstream, oiling shorelines until all of the oil was removed from the water.

Relative to the average and high river flow conditions, the CLWB is predicted to travel approximately the same distance downstream before all of the oil had adhered to the marsh or grass shoreline.

Figure 6-6 Predicted Downstream Transport of Bakken Crude Oil at the Mississippi River at Ball Club Release Location with Assumed Grass Shoreline

6.1.2.1.4 Trajectory and Fate Results for High Flow (Spring)

Under high river flow for marsh shorelines, Bakken crude was predicted to travel a total of approximately 6.4 miles (10.3 km) downstream, within 6.4 hours of the release. At this time, the model predicts that all of the oil would have been lost from the water surface; approximately 71.0% of the Bakken crude was predicted to adhere to the shorelines of the Mississippi River, and 29.0% would have evaporated into the atmosphere.

Under high river flow for the grass shorelines, Bakken crude was predicted to travel a total of approximately 23.0 miles (37.0 km) downstream, over the full 24 hour modeled period. The Bakken crude was predicted to be transported down the Mississippi River for approximately 14.9 miles (24.0 km), before reaching White Oak Lake. Bakken was allowed to spread over the

surface of the White Oak Lake (for total area of 1.47 miles^2) to a thickness of 0.001 mm. The remaining surface oil was then able to continue downstream another 6.9 miles (11.1 km). Approximately 39.8% of the Bakken crude was predicted to oil the shorelines of the Mississippi River, 0.2% would have spread over the surface of White Oak Lake, 38.4% would have evaporated into the atmosphere, and 21.6% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude on the river surface after 24 hours was expected to continue downstream, with weathering and oiling of shorelines continuing until all the oil was removed from the water surface.

The Bakken crude was predicted to result in oiling of marsh shorelines that extended 5.05 miles (8.13 km) further downstream than the CLSB scenario under high flow river conditions, which only oiled 1.35 miles (2.17 km). For grass shorelines, the Bakken crude was predicted to result in oiling 14.9 miles (24.0 km) further downstream then the CLSB (8.1 miles) under high flow river conditions.

The difference in the extent of downstream transport was primarily the result of the difference in the shoreline oil retention between the two oils. Because of its higher viscosity and other parameters, CLSB is expected to strand upon shorelines more thickly (Table 5-8) than Bakken crude oil, resulting in larger amounts of CLSB along the same length of shore. In contrast, the same amount of Bakken crude would oil longer lengths of shoreline with a reduced thickness. While this result is logical, it is based on the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point is oiled to its maximum holding capacity) as oil made its way downstream. In the event of an actual release, the downstream extents of CLSB and Bakken crude may be more similar, and the effects of CLSB may extend farther downstream than presented, with patchy coverage.

Bakken crude was predicted to evaporate much more completely (29% for marsh and 38.4% for grass) than the CLSB (0.3% for marsh and 4.8% for grass). This was partially due to the lighter nature and higher volatile content of the Bakken crude, when compared to CLSB. Additionally, the Bakken crude was predicted to oil further downstream for marsh shorelines and spread over White Oak Lake for grass shorelines, which took more time reach and also resulted in a larger surface area over which the oil could evaporate.

6.1.2.1.5 Trajectory and Fate Results for Average Flow (Summer-Fall)

Under average river flow conditions (August), Bakken crude was predicted to be transported approximately 5.7 miles (9.17 km) downstream, within 8.8 hours of the release for the marsh shorelines and approximately 15.9 miles (25.6 km) downstream, over the full 24-hour modeled period for the grass shorelines. At this time no Bakken crude was predicted to remain on the river surface; approximately 64.9% of the Bakken crude was predicted to adhere to the shorelines of the Mississippi River, and 35.1% would have evaporated into the atmosphere.

Under average river flow (August) and grass shorelines, Bakken crude was predicted to be transported approximately 15.9 miles (25.6 km) downstream, over the full 24-hour modeled period. The Bakken crude was predicted to be transported down the Mississippi River, past White

Oak Lake and stop just west of Little White Oak Lake. Approximately 30.0% of the Bakken crude was predicted to adhere to the shorelines of the Mississippi River, 43.4% to have evaporated into the atmosphere, and 26.6% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude on the river surface after 24 hours would be expected to continue downstream, with weathering and oiling of shorelines continuing until all the oil was removed from the water surface.

The Bakken crude for marsh shorelines was predicted to be transported 0.7 miles (1.13 km) less under average river flow conditions, when compared to the high river flow conditions. For grass shorelines Bakken crude was predicted to be transported 7.1 miles (11.4 km) less under average river flow conditions, when compared to the high river flow conditions. The lower river velocities of the average river flow condition, compared to the high river flow, transported the oil over less distance. The Bakken crude evaporated more completely under the average flow condition (35.1% for marsh and 43.4% for grass) when compared to the high river flow conditions (29.0% for marsh and 38.4% for grass). This difference is mainly due to the longer length of the simulation, for the average river flow conditions, as opposed to the high river flow conditions, that allowed for more time to evaporate before the end of the simulation. Additionally, the higher air temperatures during August enhanced evaporation.

When compared to the CLSB under average river flow conditions for marsh shorelines, the Bakken crude was transported 4.4 miles (7.08 km) further downstream (Bakken crude 5.7 miles, CLSB 1.31 miles). When compared to the CLSB under average river flow conditions for grass shorelines, the Bakken crude was transported 7.9 miles (12.7 km) further downstream before reaching the 24 hour model limit, with 26.6% of the Bakken crude still remaining on the river surface at the end of the simulation. The Bakken crude was able to travel further downstream than the CLSB scenario under the same river velocities due to the differences in the viscosity of the two oils and the greater adherence of CLSB to shorelines than Bakken Crude. For grass shorelines, the Bakken crude was able to travel further downstream, under the same river velocities due to the lower shoreline oil retention for the Bakken, when compared to the CLSB.

6.1.2.1.6 Trajectory and Fate Results for Low Flow (Winter)

Under low river flow (March) conditions, where oil was released underwater with 100% ice cover, Bakken crude was predicted to be transported approximately 6.5 miles (10.5 km) downstream, over the full 24-hour modeled period. Approximately 73.0% of the Bakken crude was predicted to oil the shorelines of the Mississippi River, and the remaining 27.0% would remain in the river below the ice at the end of the 24 hour simulation for marsh shorelines. Approximately 12.2% of the Bakken crude for grass shorelines was predicted to adhere to the shorelines of the Mississippi River, and the remaining 87.8% would remain in the river, below the ice at the end of the 24 hour simulation. If left unmitigated, it is expected that the remaining Bakken crude in the river after 24 hours would continue to move downstream and oil shorelines, until all the oil was removed from the water surface (i.e., under the ice).

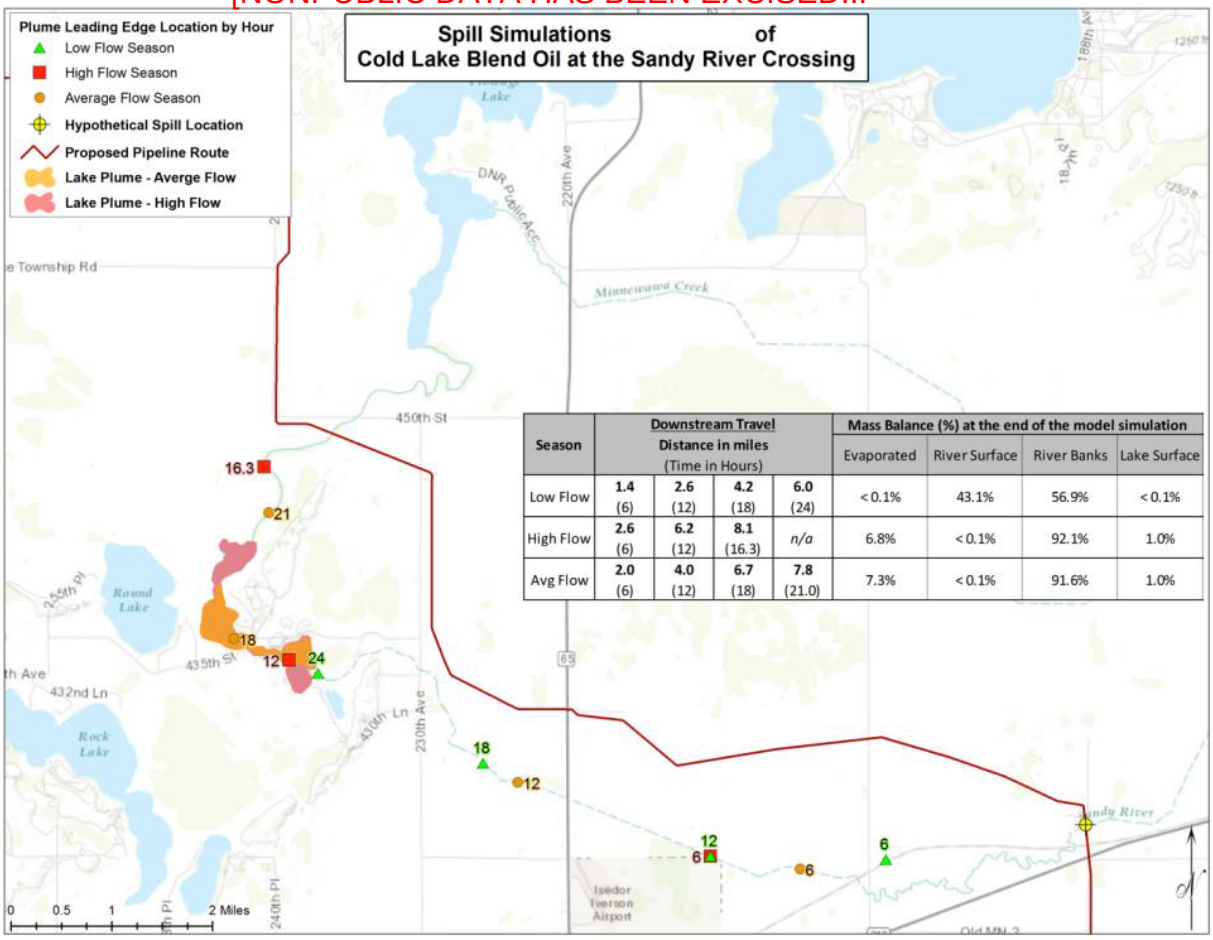
Relative to the high river flow conditions, the Bakken crude for the marsh shorelines was predicted to be transported 0.1 miles (0.16 km) further downstream. Relative to the average river flow conditions, the Bakken crude was predicted to be transported 0.8 miles (1.29 km) further downstream. Under low river flow conditions the shore types were conservatively assumed to be the same as the average flow condition. Retention of oil under ice conditions may be lower or higher in reality, but is expected to be variable due to irregularities in the ice and the ice/shoreline interface Rather than having an extent controlled by the loss of all surface oil, this scenario reached the 24 hour modeled time limit.

Relative to the high river flow condition, the Bakken crude for grass shorelines was predicted to be transported 16.5 miles (26.6 km) less downstream. Relative to the average river flow condition, the Bakken crude was predicted to be transported 9.4 miles (15.1 km) less downstream. Due to the winter conditions, the oil was transported at a slower velocity and therefore traveled a shorter distance then than the average and high river flow conditions. Because the Bakken crude was released below the ice of the river, no oil is lost to the atmosphere through evaporating. This further extended the potential downstream transport. With the oil being transported at a slower velocity, the 24 hour modeled time limit was reached before oil was lost to shorelines or evaporation. Additionally, with the Bakken crude below the ice of the river, no oil is lost to the atmosphere through evaporating.

The Bakken crude for grass shorelines under low flow river conditions was transported 5.15 miles (8.29 km) further downstream than the CLWB for the same conditions. The Bakken crude was able to travel further downstream, under the same river velocities due to the lower shoreline oil retention for Bakken, compared to CLWB. For this reason 27% more oil can be transported downstream under the ice.

6.1.3 Unmitigated Hypothetical Release Case 3—Sandy River

The Sandy River is located approximately 1 mile (1.6 km) north of McGregor, Minnesota. The pipeline route crosses the Sandy River approximately 3.3 miles (5.3 km) north east of McGregor, and 0.2 miles (0.32 km) north of Highway 210. The Sandy River flows to the west for approximately 6 miles (9.7 km) before reaching Steamboat Lake and Davis Lake. This stretch of the river is fairly narrow (approximately 40 ft wide, or 12.2 m, on average), and travels through several marshy areas. From there, the Sandy River flows to the north an additional 3.5 miles (5.6 km) where it enters Flowage Lake. The Sandy River for this stretch can average 53 ft (16.2 m) wide during low river flow conditions, and average 270 ft (82.3 m) wide during high flow conditions.



The seasonal extent of Steamboat, Davis, and Flowage Lakes also vary from low to high river flow conditions. During low and average river flow conditions, the area of Steamboat Lake is 0.036 miles^2 (0.093 km^2), and during high river flow conditions the area is typically 0.065 miles^2 (0.168 km^2). During low and average river flow conditions, the area of Davis Lake is 0.07 miles^2 (0.181 km^2), and during high river flow conditions the area is typically 0.117 miles^2 (0.303 km^2). During low river flow conditions, Sandy River does not join Flowage Lake until approximately

7 miles (11.3 km) north of Davis Lake. Under high river flow conditions, Sandy River transitions to Flowage Lake after approximately 3.5 miles (5.63 km). Expected environmental and flow conditions throughout the year for Sandy River are provided in Table 5-6.

Maps depicting the predicted downstream trajectory and mass balance tables of CLB (Figure 6-7) and Bakken Crude (Figure 6-8) seasonal scenarios for the Sandy River release site are provided at the beginning of the following subsections.

6.1.3.1 Cold Lake Blend Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Season	Downstream Travel Distance in miles (Time in Hours)				Mass Balance (%) at the end of the model simulation

Figure 6-7 Predicted Downstream Transport of CLB Oil at the Sandy River Release Location

6.1.3.1.1 Trajectory and Fate Results for High River Flow (Spring)

Flow rates for Sandy River during the spring resulted in peak average river velocities during April ranging between 0.35 and 0.89 mph (0.16 and 0.4 m/s). The OILMAP Land model transported oil downstream with these velocities to a point where all oil had evaporated and/or adhered to the shoreline.

Under high river flow conditions, CLSB was predicted to travel a total of approximately 8.1 miles (13.0 km) downstream, within 16.3 hours of the release. At this time, there was no CLSB on the water surface, as the model had predicted that the oil would have been lost completely from the water surface by this point in time. The CLSB was predicted to be transported down the Sandy River, then spread covering the surfaces of both Steamboat Lake and Davis Lake (for a total area of 0.182 miles^2 or 0.471 km^2), and then continue another 0.7 miles (1.12 km) down Sandy River. Approximately 92.1% of the CLSB was predicted to oil the shorelines of Sandy River, 1.0% to have spread over the surface of Steamboat and Davis Lakes, and 6.8% to have evaporated into the atmosphere.

6.1.3.1.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

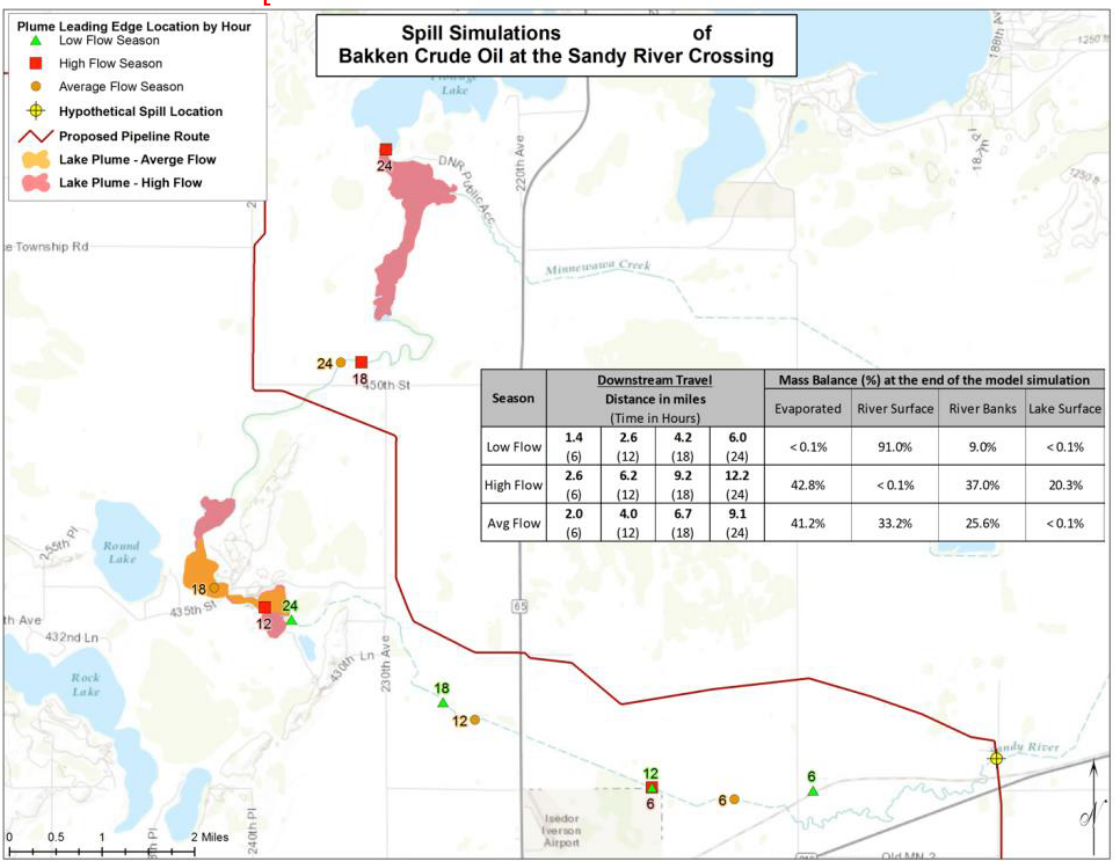
Flow rates for Sandy River during the summer and fall result in average river velocities during July ranging between 0.27 and 0.60 mph (0.12 and 0.27 m/s). These river velocities were approximately 70% of those in the high flow conditions.

Under average river flow conditions, CLSB was predicted to travel a total of 7.8 miles (12.6 km) downstream, within 21 hours of the release. At this time, there was no CLSB on the water surface, as the model predicted that the oil would have been lost from the water surface by this point in time. The CLSB was predicted to be transported down the Sandy River, then spread covering the surfaces of both Steamboat Lake and Davis Lake (for total area of 0.106 miles^2 or 0.275 km^2), and then continue another 0.7 miles (1.12 km) in Sandy River. Approximately 91.6% of the CLSB was predicted to adhere to the shorelines of Sandy River, 1.0% to have spread over the surface of Steamboat and Davis Lakes, and 7.3% to have evaporated into the atmosphere.

Relative to the high river flow condition, the CLSB was predicted to be transported less distance downstream (0.3 miles or 0.48 km). This was predominantly due to the length of the scenario which allowed for more evaporation due to the longer time required for the CLSB to move down stream due to the lower stream velocities. Under both high and average flow conditions, oil spread over the entire surface of both Davis and Steamboat Lakes, however the area of the lakes was smaller in the average flow condition. The slightly reduced area of the lakes only accounts for approximately 0.01% difference in the volume remaining on the lakes.

6.1.3.1.3 Trajectory and Fate Results for Low River Flow (Winter)

Under winter conditions (March), it was assumed that the Sandy River and all lakes would be frozen over completely (100% coverage of ice). It was assumed that CLWB would be released directly into the river from the pipeline under the riverbed, and that all oil would remain trapped under the ice. The ice cover would prevent any evaporation to the atmosphere. Flow rates for



Sandy River during these winter conditions resulted in minimum river velocities during March ranging between 0.20 and 0.31 mph (0.09 and 0.14 m/s). These river velocities were approximately 50% of that of the high flow condition.

Under low river flow conditions, CLWB was predicted to be transported a total of 6.0 miles (9.7 km) downstream, over the full 24-hour modeled period. The CLWB was predicted to stop just before reaching Steamboat Lake. Approximately 43.1% of the CLWB was predicted to remain in the river below the ice, and the remaining 56.9% would have oiled the shorelines of Sandy River. Any CLWB remaining in the river after 24 hours would continue to move downstream, oiling shorelines and Steamboat Lake, if not intercepted by emergency response teams.

Relative to the high and average river flow conditions, the CLWB was predicted to be transported over a shorter distance, stopping before reaching Steamboat Lake. This was due to the reduced river velocities under the low river flow conditions.

6.1.3.2 Bakken Crude Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Season	Downstream Travel Distance in miles (Time in Hours)				Mass Balance (%) at the end of the model simulation			
					Evaporated	River Surface	River Banks	Lake Surface

...NONPUBLIC DATA HAS BEEN EXCISED]

Figure 6-8 Predicted Downstream Transport of Bakken Crude Oil at the Sandy River Release Location

6.1.3.2.1 Trajectory and Fate Results for High River Flow (Spring)

Under high river flow (April), Bakken crude was predicted to be transported approximately 12.2 miles (19.6 km) downstream, over the full 24-hour modeled period. The Bakken crude was predicted to be transported down the Sandy River, and then spread covering the surfaces of both Steamboat Lake and Davis Lake (for total area of 0.182 miles^2 or 0.471 km^2). It was then able to continue another 3.5 miles (5.6 km) in Sandy River, before reaching Flowage Lake. Oil was predicted to spread over the surface of Flowage Lake covering an area of approximately 0.22 miles^2 or 0.570 km^2. Approximately 37.0% of the Bakken crude was predicted to adhere to the shorelines of Sandy River, 20.3% would have spread over the surface of Steamboat, Davis, and Flowage Lakes, and 42.8% would have evaporated into the atmosphere.

OILMAP Land spreads the mass of oil entering the lake radially upon the lake surface until the specified minimum slick thickness is reached, or the simulation duration is reached. This modeling tool is used to characterize regions of potential effects on relatively short time scales (i.e., hours

to days). After 24 hours, the Bakken crude oil did not yet spread in Flowage Lake to the defined minimum thickness of 0.001 mm (Table 5-9). If left unmitigated, it is expected that this spreading would continue to occur after 24 hours, covering a larger surface area of the lake.

The Bakken crude was predicted to result in oiling 4.1 miles (6.6 km) further downstream, then the CLSB (8.1 miles or 13.0 km) under high flow river conditions. The difference in the extent of downstream transport was primarily the result of the differences in the shoreline and lake surface oil retention between the two oil types. Because of its higher viscosity and other parameters, CLSB would be expected to strand upon shorelines and spread on a lake surface more thickly than Bakken crude oil, resulting in larger amounts of CLSB along the same area. In contrast, the same amount of Bakken crude would oil longer lengths of shoreline and more lake surface, but with a reduced thickness. While this result is logical, it is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point is oiled to its maximum holding capacity) as oil makes its way downstream, and the assumption that oil would spread evenly within lake. In the event of an actual release, the downstream extents of CLSB and Bakken crude may be more similar, and the effects of CLSB may extend farther downstream than presented, with patchy coverage.

Due mostly to the lighter nature and higher volatile content, Bakken crude was predicted to evaporate over 6 times more (42.8%) than the CLSB (6.8%). The Bakken crude was predicted to oil further downstream, which took more time and resulted in a larger surface area over which the oil would evaporate.

6.1.3.2.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

Under average river flow (July), Bakken crude was predicted to be transported approximately 9.1 miles (14.6 km) downstream, over the full 24-hour modeled period. The Bakken crude was predicted to be transported down the Sandy River, and then spread covering the surfaces of both Steamboat Lake and Davis Lake (for total area of 0.106 miles^2 or 0.274 km^2). It was then able to continue another 2.05 miles (3.3 km) down Sandy River. Approximately 25.6% of the Bakken crude was predicted to adhere to the shorelines of Sandy River, less than 0.1% would have spread over the surface of Steamboat and Davis Lakes, 41.2% would have evaporated into the atmosphere, and 33.2% would remain on the river surface at the end of the 24 hour simulation. If left unmitigated, it is expected that the remaining Bakken crude on the river surface would continue downstream, with weathering and oiling of shorelines continuing until all the oil is removed from the water surface.

The Bakken crude was predicted to be transported 3.1 miles (5.0 km) less when compared to the high river flow conditions. The lower river velocities of the average river flow condition prevented the oil from being transported as far downstream within the 24 hour simulation period. The Bakken crude evaporated less in the average flow condition (41.2 %) than the high flow condition (42.8%) due to the reduced surface area oiled. This was a result of smaller area of Steamboat and Davis Lakes, and the reduced downstream transport.

When compared to the CLSB under average river flow conditions, the Bakken crude was transported 3 miles (4.8 km) further downstream before reaching the 24 hour model limit. Approximately 33.2% of the Bakken crude was still remaining on the river surface at the end of the simulation. The Bakken crude was able to travel further downstream, under the same river velocities due to the differences in the shoreline and lake surface oil retention between the two oil types.

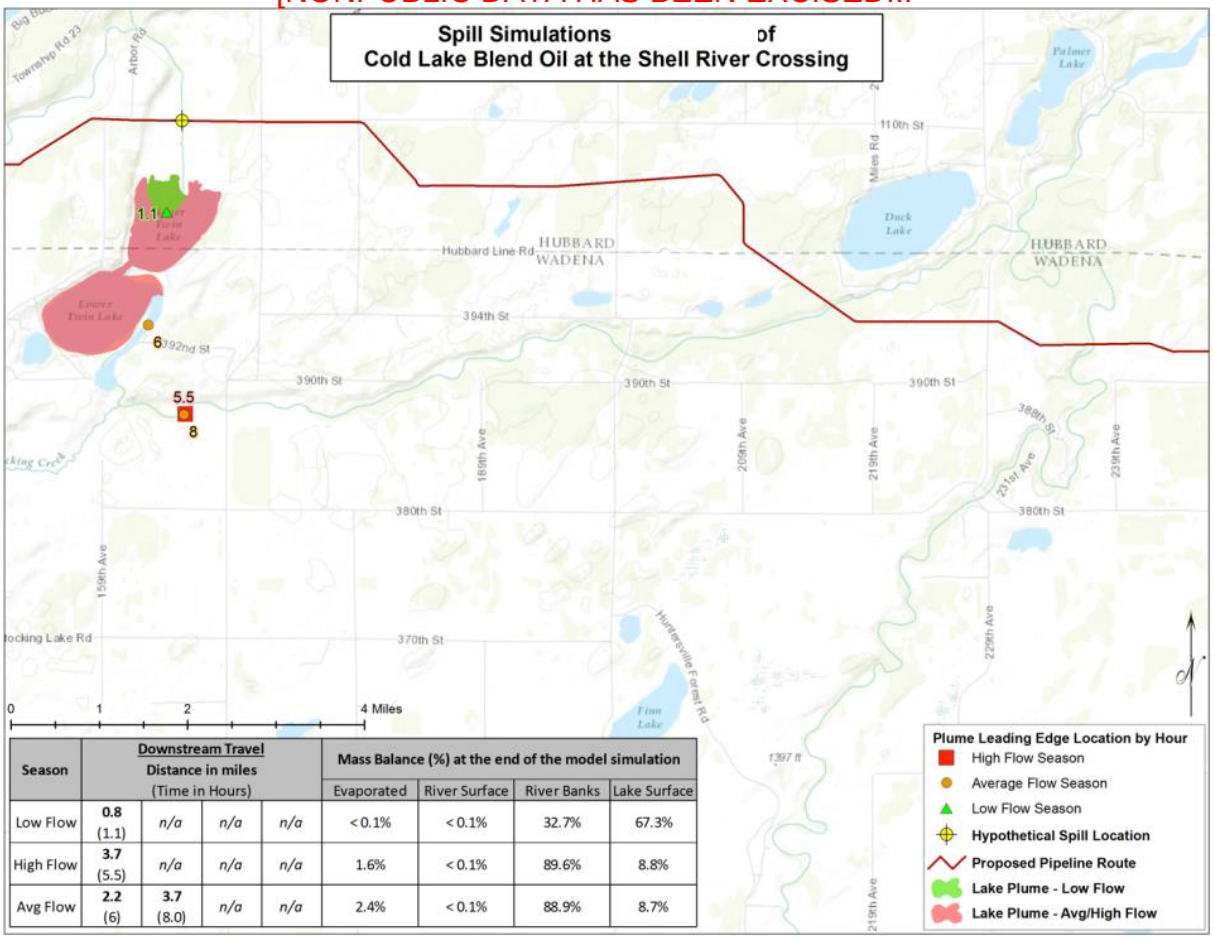
6.1.3.2.3 Trajectory and Fate Results for Low River Flow (Winter)

Under low river flow conditions (March), released under 100% ice cover, Bakken crude was predicted to be transported a total of 6.0 miles (9.7 km) downstream, over the full 24-hour modeled period to a point just before Steamboat Lake. Approximately 91.0% of the Bakken crude was predicted to remain in the river below the ice, and the remaining 9.0% to adhere to the shorelines of Sandy River. If not intercepted by emergency response teams, the remaining Bakken crude in the river after 24 hours would be expected to move downstream, oiling shorelines and Steamboat Lake.

Relative to the high river flow conditions, the Bakken crude under low river flow was predicted to be transported 6.2 miles (10.0 km) less downstream. Relative to the average river flow condition, the Bakken crude was predicted to be transported 3.1 miles (5.0 km) less downstream. Under low river flow conditions, the shore types were conservatively assumed to be the same as the average flow condition. Retention of oil under ice conditions may be lower or higher in reality, but is expected to be variable due to irregularities in the ice and the ice/shoreline interface With the oil being transported at a slower speed, the 24 hour modeled time limit was reached at a distance that was shorter than that of the average river flow condition with oil remaining on the surface. With the Bakken crude below the ice of the river, no oil was allowed to evaporate from the surface.

When compared to the CLWB under low river flow conditions, 47.9% more of the Bakken crude remained in the river and under the ice. This was due to the lower shoreline oil retention for Bakken, relative to the CLWB.

6.1.4 Unmitigated Hypothetical Release Case 4—Shell River to Twin Lakes



Shell River is located approximately 7.4 miles (11.9 km) south of Park Rapids, Minnesota. The pipeline route crosses the Shell River and Crow Wing River at four locations. The crossing used for this release location is the eastern crossing of the Shell River located 0.6 miles (0.97 km) north of Twin Lakes and 0.75 miles (1.21 km) southeast of Arbor Road. At this location the Shell River flows directly south where it reaches the Twin Lakes (Upper Twin Lake and Lower Twin Lake). This section of the Shell River passes through a large marshy area, north of the lakes and is approximately 95 ft (29 m) wide. The Twin Lakes cover a total area of approximately 0.75 miles^2 (1.94 km^2). The outlet from Lower Twin Lake is located at the northeastern edge of the lake. From there Shell River flows to the west for approximately 9 miles (14.5) before flowing into the Crow Wing River. This stretch of river has an average width of 223 ft (68 m). From there, the Crow Wing

River flows to the south through Huntersville State Forest at an average width of 184 ft (56 m). Expected environmental and flow conditions throughout the year for Shell River/ Crow Wing River are provided in Table 5-6.

Maps of the predicted downstream trajectory and mass balance tables of CLB (Figure 6-9) and Bakken Crude (Figure 6-10) seasonal scenarios for the Shell River to Twin Lakes release site are provided at the beginning of the following subsections.

6.1.4.1 Cold Lake Blend Scenarios

...NONPUBLIC DATA HAS BEEN EXCISED]

Figure 6-9 Predicted Downstream Transport of CLB Oil at the Shell River Release Location

6.1.4.1.1 Trajectory and Fate Results for High River Flow (Spring)

Flow rates for Shell River during the spring (April) result in peak average river velocities ranging between 0.85 and 2.26 mph (0.38 and 1.01 m/s). The OILMAP Land model transported oil downstream with these velocities to a point where all oil had evaporated and/or adhered to the shoreline.

Under high river flow, CLSB as predicted to travel a total of approximately 3.7 miles (6.0 km) downstream, within 5.5 hours of the release. At this time there was no CLSB on the river surface as the model predicted that the oil would have been lost from the water surface by this point in time. The CLSB was predicted to be transported down the Shell River 0.6 miles (0.97 km), then spread, covering the surfaces of both Upper and Lower Twin Lakes (for total area of 0.75 miles^2 or 1.94 km^2) to a thickness of 0.1 mm (Table 5-8), and then continue another 1.8 miles (2.9 km)down the Shell River. Approximately 89.6% of the CLSB was predicted to adhere to the shorelines of Shell River, 8.8% to have spread over the surface of Upper and Lower Twin Lake, and 1.6% to have evaporated into the atmosphere.

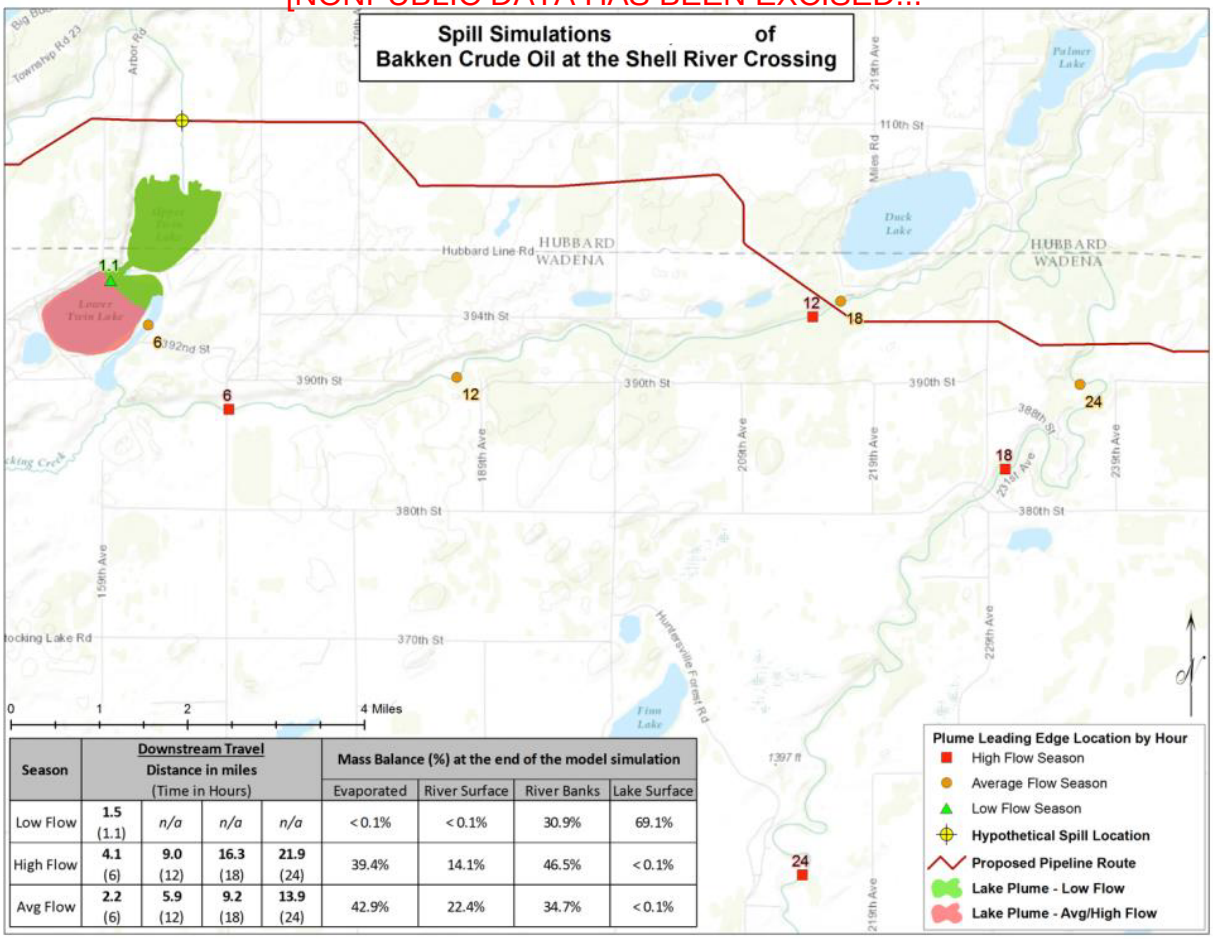
6.1.4.1.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

Flow rates for Shell River during the summer and fall result in average river velocities during August ranging between 0.58 and 1.3 mph (0.26 and 0.62 m/s). These river velocities were approximately 68% of that of the high flow condition.

As in the high river flow condition, CLSB under average river flow was predicted to travel a total of approximately 3.7 miles (6.0 km) downstream. However, under average river flow conditions with lower stream velocities, it took approximately 8.0 hours to reach this same distance. At this time there was no CLSB on the river surface as the model predicted that the oil would have been lost from the water surface by this point in time. The CLSB was predicted to be transported down the Shell River 0.6 miles (0.97 km), then spread covering the surfaces of both Upper and Lower Twin Lake (for total area of 0.75 miles^2 or 1.94 km^2) to a thickness of 0.1 mm (Table 5-9), and then continue another 1.8 miles (2.9 km) down the Shell River. Approximately 88.9% of the CLSB was predicted to adhere to the shorelines of Shell River, 8.7% to have spread over the surface of Upper and Lower Twin Lake, and 2.4% to have evaporated into the atmosphere.

Relative to the high river flow condition, more of the CLSB was predicted to evaporate. This was partially due to the higher temperatures in the summer conditions, but mainly due to the longer time required for the CLSB to move down stream due to the lower stream velocities. The slight reduction in oil remaining on the river shoreline and lake surface in the average river flow condition was the result of this increase in evaporation.

6.1.4.1.3 Trajectory and Fate Results for Low River Flow (Winter)



Under winter conditions (March), it was assumed that Shell River and Twin Lakes would be frozen over completely (100% coverage of ice). Additionally, it was assumed that CLWB would be released directly into the river from the pipeline under the river bottom, and remained trapped under the ice. The ice cover would prevent any evaporation to the atmosphere. Flow rates for

Shell River during these winter conditions resulted in minimum river velocities during March with a value of 0.56 mph (0.25 m/s). These river velocities were approximately 55% that of the high flow conditions.

Under low river flow conditions, the CLWB was predicted to be transported down the Shell River for 0.6 miles (0.97 km), and then spread under the ice to a thickness of 10.6 mm (Table 5-9; Section 5.3.2.6). CLWB was predicted to be transported a total of 0.8 miles (1.29 km) downstream, within 1.1 hours of the release. The oil was predicted to spread under the ice covering an area of 0.054 miles^2 (0.140 km^2) of Upper Twin Lake. Approximately 32.7% of the CLWB was predicted to adhere to the shorelines of Shell River, and the remaining 67.3% to spread under the ice within the lake. Relative to the high and average river flow conditions, the CLWB was predicted to be transported 2.9 miles (4.7 km) less downstream. This was due to the increased capacity for the ice to trap CLWB (10.6 mm) under the frozen surface of the lake.

6.1.4.2 Bakken Crude Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Season	Downstream Travel Distance in miles (Time in Hours)				Mass Balance (%) at the end of the model simulation			
					Evaporated	River Surface	River Banks	Lake Surface
Low Flow	1.5 (1.1)	*n/a*	*n/a*	*n/a*	< 0.1%	< 0.1%	30.9%	69.1%
High Flow	4.1 (6)	9.0 (12)	16.3 (18)	21.9 (24)	39.4%	14.1%	46.5%	< 0.1%
Avg Flow	2.2 (6)	5.9 (12)	9.2 (18)	13.9 (24)	42.9%	22.4%	34.7%	< 0.1%

...NONPUBLIC DATA HAS BEEN EXCISED]

Figure 6-10 Predicted Downstream Transport of Bakken Crude Oil at the Shell River Release Location

6.1.4.2.1 Trajectory and Fate Results for High River Flow (Spring)

Under high river flow (April), Bakken crude was predicted to be transported approximately 21.9 miles (35.2 km) downstream, over the full 24-hour modeled period. The Bakken crude was predicted to be transported down the Shell River, and then spread covering the surfaces of both Upper and Lower Twin Lake (for total area of 0.75 miles^2 or 1.94 km^2) to a thickness of 0.001 mm (Table 5-9). It was then able to continue another 20.0 miles (32.2 km) down Shell River and Crow Wing River. Approximately 46.5% of the Bakken crude was predicted to oil the shorelines of Shell River and Crow Wing River, less than 0.1% would have spread over the surface of Upper and Lower Twin Lake, 39.4% to have evaporated into the atmosphere, and 14.1% to remain on the

river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude on the river surface after 24 hours would be expected to continue downstream, weathering and oiling of shorelines until all the oil was removed from the water surface.

The Bakken crude was predicted to result in oiling 18.2 miles (29.3 km) further downstream than the CLSB (3.9 miles) under high flow river conditions. The difference in the extent of downstream transport was primarily the result of the differences in the shoreline and lake surface oil retention between the two oil types. Because of its higher viscosity and other parameters, CLSB would be expected to strand upon shorelines and spread on a lake surface more thickly than Bakken crude oil, resulting in larger amounts of CLSB along the shore and lake surface. In contrast, the same amount of Bakken crude would oil longer lengths of shoreline and more lake surface with a reduced thickness. While this result is logical, it is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point is oiled to its maximum holding capacity) as oil makes its way downstream, and the assumption that oil would spread evenly within lake. In the event of an actual release, the downstream extents of CLSB and Bakken crude may be more similar, and the effects of CLSB may extend farther downstream than presented, with patchy coverage.

Bakken crude was predicted to evaporate nearly 25 times more (39.4%) than the CLSB (1.6%). This was partially due to the lighter nature and higher volatile content of the Bakken crude. Additionally, the Bakken crude was predicted to oil further downstream, which took more time and resulted in more surface area with oil. The additional time for downstream transport and oiled surface area allowed for more oil to evaporate to the atmosphere.

6.1.4.2.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

Under average river flow (August), Bakken crude was predicted to be transported approximately 13.9 miles (22.4 km) downstream, over the full 24-hour modeled period. The Bakken crude was predicted to be transported down the Shell River, and then spread covering the surfaces of both Upper and Lower Twin Lake (for total area of 0.75 miles^2 or 1.94 km^2) to a thickness of 0.001 mm (Table 5-9). It then continued another 12.0 miles (19.3 km) down the Shell River and Crow Wing River. Approximately 34.7% of the Bakken crude was predicted to adhere to the shorelines of Shell River and Crow Wing River, less than 0.1% to have spread over the surface of Upper and Lower Twin Lake, 42.9% to have evaporated into the atmosphere, and 22.4% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude on the river surface after 24 hours would be expected to continue downstream.

The Bakken crude was predicted to be transported 8 miles (12.9 km) less under average river flow conditions (13.9 miles or 22.4 km), when compared to the high river flow conditions (21.9 miles or 35.2 km). The lower river velocities of the average river flow condition prevented the oil from being transported as far within the 24 hour simulation period. The Bakken crude evaporated more under the average flow conditions (42.9%) than the high flow conditions (39.4%) due to the higher air temperatures. The higher air temperature causes the Bakken crude

to evaporate more in the same 24 hour period despite the surface area being oiled being higher in the high river flow condition.

When compared to the CLSB under average river flow conditions (3.7 miles or 6.0 km), the Bakken crude is transported 10.2 miles (16.4 km) further downstream before reaching the 24 hour model limit. Additionally 22.4% of the Bakken crude was remaining on the river surface at the end of the simulation. The Bakken crude was able to travel further downstream, under the same river velocities due to the differences in the shoreline and lake surface oil retention between the two oil types.

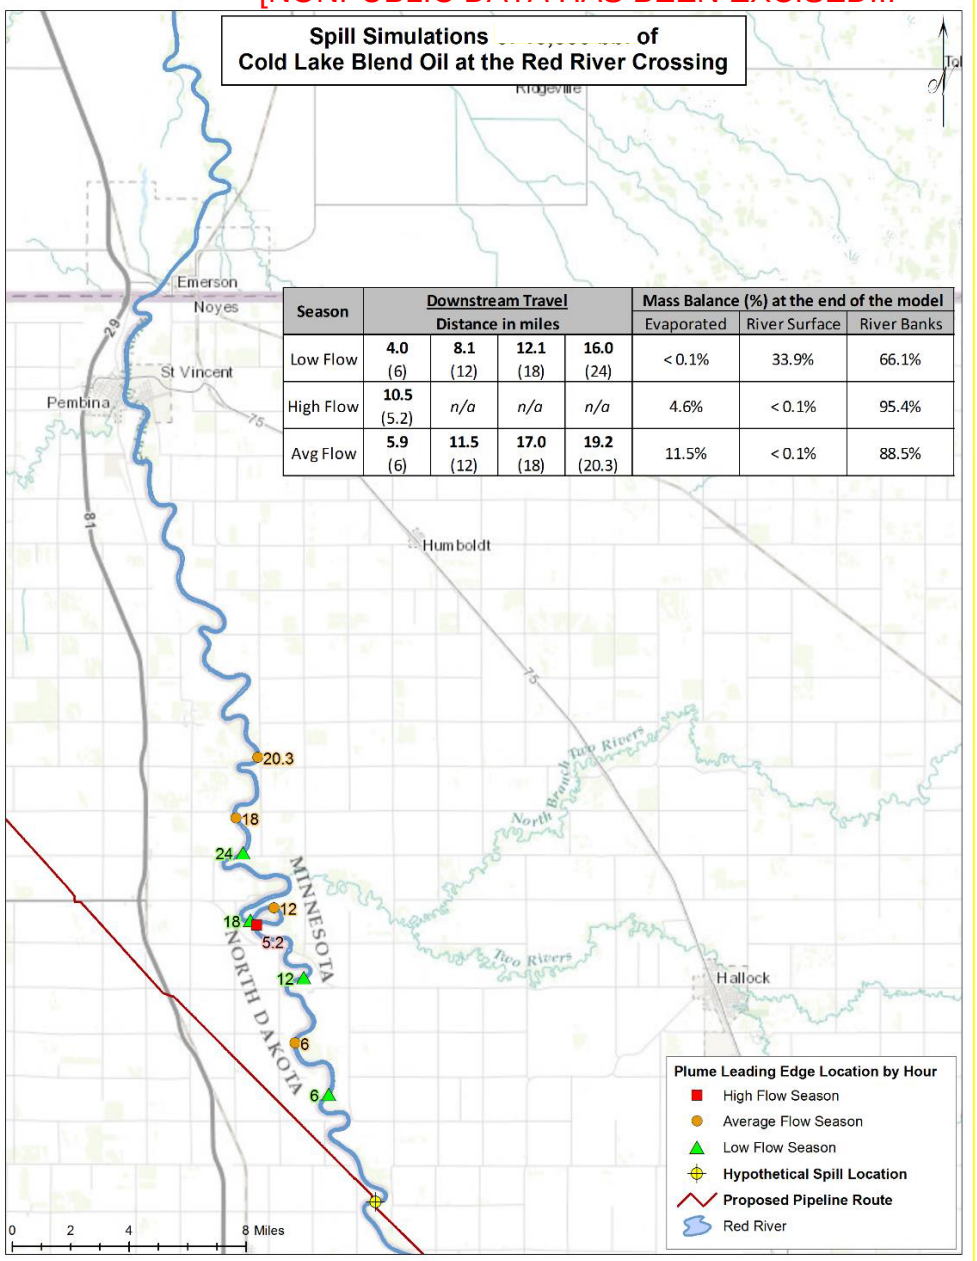
6.1.4.2.3 Trajectory and Fate Results for Low River Flow (Winter)

Under low river (March) flow conditions, with oil released underneath 100% ice cover, Bakken crude was predicted to be transported a total of 1.5 miles (2.4 km) downstream, within 1.1 hours of the release. The Bakken crude was predicted to be transported down the Shell River for 0.6 miles (0.97 km), and then spread under the ice to a thickness of 1.9 mm (Table 5-9). The oil was predicted to spread under the ice covering an area of 0.42 miles^2 (1.09 km^2) including all of Upper Twin Lake and a portion of Lower Twin Lake. Approximately 30.9% of the Bakken crude was predicted to oil the shorelines of Shell River, and the remaining 69.1% to spread under the ice within the lake.

When compared to the CLWB under low river flow conditions (32.7%), 1.8% less of the Bakken crude remained on the river shorelines under the ice. This was due to the lower shoreline oil retention for Bakken crude oil, compared to CLWB. For this reason 1.8% more oil was able to spread under the ice surface in Upper and Lower Twin Lake for the Bakken release. The Bakken crude was also able to spread in the lakes under the ice to a greater extent (0.42 miles^2) than the CLWB (0.054 miles^2 or 0.140 km^2) due to the reduced capacity of the ice to trap the Bakken crude.

6.1.5 Unmitigated Hypothetical Release Case 5—Red River

The Red River is located along the border of Minnesota and North Dakota, and runs to the north into Canada. The pipeline crossing is located approximately 3 miles (4.82 km) due east of Bowesmont, North Dakota and 9 miles (14.48 km) southwest of Hallock, Minnesota adjacent to Route 16. At the proposed pipeline crossing location and downstream, the Red River is a large, wide (150-400 ft) river that flows north along a well-defined sinuous channel. The Red River passes the communities of Pembina, North Dakota and St. Vincent, Minnesota approximately 32 river miles downstream from the crossing location, and crosses into Canada approximately 34.5 miles downstream. The communities of Emerson and West Lyme, Manitoba are located on the Canadian side of the international border.



This modeling site captures a large, low-gradient (dropping approximately 6 ft in 35 river miles) watercourse, with a sinuous channel that is subject to flooding. The shore types are predominantly vegetated, often with shrubs and trees above the level of ice-scour. These waters

are known to be a major area for recreation use, and also pass through or adjacent to sensitive ecosystems. The riparian banks are generally well vegetated, including some trees. Patches of forest are often present where the river meanders, although the surrounding land use is primarily agricultural. The Red River is subject to moderate to extreme flooding, particularly in the spring. Under low or average flow conditions, the stream banks are a combination of grass and soil. Under higher flow conditions the river can overtop the banks and spread into the surrounding farm and grassland. Expected environmental conditions throughout the year for the Red River are provided in Table 5-6.

The predicted downstream trajectory and mass balance tables for CLB (Figure 6-11) and Bakken crude (Figure 6-12) seasonal scenarios for the Red River release location are provided.

6.1.5.1 Cold Lake Blend Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Season	Downstream Travel Distance in miles				Mass Balance (%) at the end of the model

...NONPUBLIC DATA HAS BEEN EXCISED]

Figure 6-11 Predicted Downstream Transport of CLB Oil at the Red River Release Location

6.1.5.1.1 Trajectory and Fate Results for High River Flow (Spring)

Flow rates for the Red River during the spring result in peak average river velocities during April ranging from 1.97 and 4.12 mph (0.88 and 1.84 m/s). The OILMAP Land model transports oil downstream with these velocities to a point where all oil has evaporated and/or adhered to the shoreline.

Under high river flow, CLB was predicted to travel a total of approximately 10.5 miles (16.9 km) downstream, within 5.2 hours of the release. At this time, there was no CLB on the river surface as the model predicted that the oil would have been lost from the water surface by this point in time. After this distance, the oil would have been transported to the north through agricultural lands, stopping before the confluence with the Two Rivers. Approximately 95.4% of the CLB would be predicted to oil the shorelines of the Red river, and the remaining 4.6% would have evaporated into the atmosphere.

6.1.5.1.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

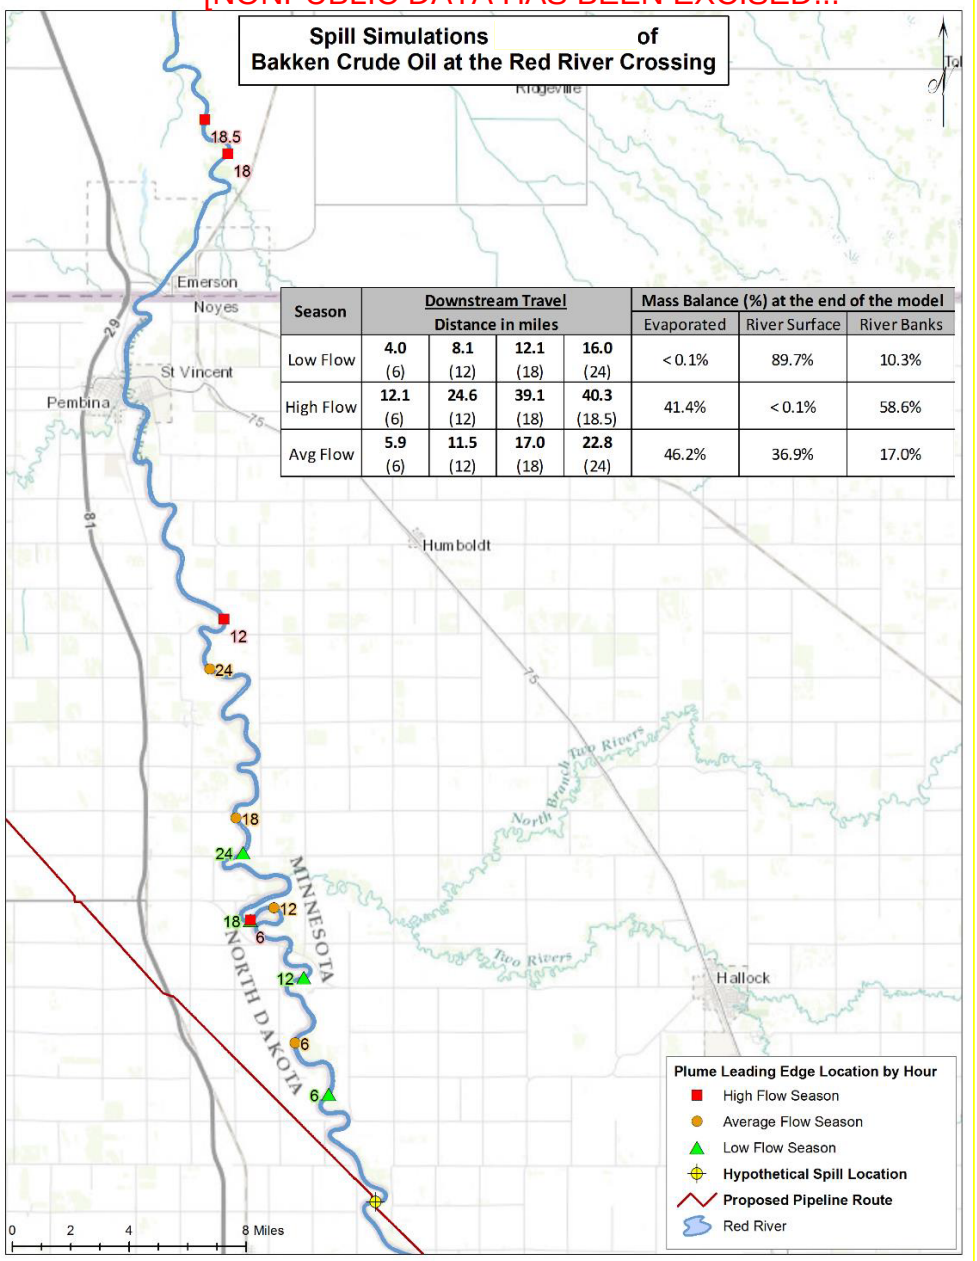
Flow rates for the Red River during the summer (August) and fall resulted in average river velocities ranging between 0.94 and 1.81 mph (0.42 and 0.81 m/s). These river velocities were approximately 43% of that of the high flow condition.

Under average river flow, CLB was predicted to travel a total of approximately 19.2 miles (30.9 km) downstream, within 20.3 hours of the release. At this time there would be no CLB on the river surface as the model predicted that the oil would have been lost from the water surface by this point in time. After 19.2 miles (30.9 km) the oil would have been transported to the north, passed the confluence with the Two Rivers to roughly a point just north of 310th Street in Minnesota, where County Ditch Number 26 enters the Red River. Approximately 88.5% of the CLB was predicted to oil shorelines of the Red River, and 11.5% to evaporate into the atmosphere.

Relative to the high river flow condition, the CLB was predicted to travel further downstream under average flow conditions. Under average flow conditions the stream shorelines are predominantly a mixture of grass and soil. Under high flow conditions all of the stream shorelines are assumed to be underwater and the shore type would be grass. The soil shorelines are capable of retaining 15 m^3 of CLB per kilometre of river, while the grass shoreline is capable of retaining 125 m^3 of CLB per kilometre of river. In the average river flow condition, less of the CLB would have adhered to the soil shorelines, allowing it to be transported further downstream. The volume of oil retained on the shoreline was less under the average flow conditions because more of the CLB was able to evaporate. This was partially due to the higher temperatures in the summer/fall conditions, but mainly driven by the longer time the CLB was able to move downstream and the greater surface area containing oil that was able to evaporate.

6.1.5.1.3 Trajectory and Fate Results for Low River Flow (Winter)

The lowest river flow winter conditions for the Red River occurs in February. To maximize downstream oiling potential, it was conservatively assumed that the Red River would be frozen over completely (100% coverage of ice). It was assumed that CLWB would be released directly



into the river from the pipeline, which was under the river bed, and that all oil would remain trapped under the ice. The ice cover would prevent any evaporation to the atmosphere. Flow rates for the Red River during these winter conditions resulted in river velocities that ranged between 0.65 and 1.21 mph (0.29 and 0.54 m/s).

Under low river flow conditions, CLWB was predicted to be transported a total of 16.0 miles (25.7 km) downstream, over the full 24-hour modeled period. Approximately 66.1% of the CLWB was predicted to oil shorelines of the Red River, and the remaining 33.9% to remain in the river below the ice at the end of the 24 hour simulation. If left unmitigated, the remaining CLWB in the river after 24 hours would be expected to continue downstream, oiling shorelines until all of the oil was removed from the water surface. At the end of the 24-hour model period the CLWB was predicted to reach just north of 290th Street in Minnesota.

Relative to the high river flow conditions, the CLWB was predicted to be transported 5.5 miles (8.9 km) further downstream. Relative to the average river flow condition, the CLWB was predicted to be transported 3.2 miles (5.1 km) fewer downstream. Under low river flow conditions, the shore types were assumed to be the same as the average flow conditions. With the oil being transported at a lower velocity, 24 hour modeled time limit was reached at a shorter distance than the average river flow condition. With the CLWB below the ice of the river, no oil was evaporating from the surface.

6.1.5.2 Bakken Crude Scenarios

[NONPUBLIC DATA HAS BEEN EXCISED...

Figure 6-12 Predicted Downstream Transport of Bakken Crude Oil at the Red River Release Location

6.1.5.2.1 Trajectory and Fate Results for High River Flow (Spring)

Under high river flow, Bakken crude was predicted to be transported approximately 40.3 miles (64.9 km) downstream, within 18.5 hours of the release. At this time there was no Bakken crude on the river surface as the model predicted that the oil would have been lost from the water surface by this point in time. After 40.3 miles (64.9 km) the oil has been transported to the north, past Pembina, into Canada, past Emerson and the confluence of the Joe River and terminating before the Ginew Roseau River Reserve. Approximately 58.6 of the Bakken crude was predicted to oil shorelines of the Red River and 41.4% to evaporate into the atmosphere.

The Bakken crude was predicted to result in oiling 29.8 miles (48.0 km) further downstream than the CLB (10.5 miles or 16.9 km) under high flow river conditions. The difference in the extent of downstream transport was the result of the differences in the shoreline oil retention between the two oil types. Because of its higher viscosity and other parameters, CLB was expected to strand upon shorelines more thickly than Bakken crude oil, resulting in larger amounts of CLB along the shore. In contrast the same amount of Bakken crude would oil longer lengths of shoreline with a reduced thickness. While this result is logical, it is based upon the assumption of 100% shoreline oiling coverage (i.e. all shoreline up to that point is oiled to its maximum holding capacity) as oil makes its way downstream. In the event of an actual release, the downstream extents of CLB and Bakken crude may be more similar, and the effects of CLB may extend farther downstream than presented, with patchy coverage.

Bakken crude was predicted to evaporate approximately 9 times more (41.4%) than the CLB (4.6%). This was partially due to the lighter nature and higher volatile content of the Bakken crude. Additionally, the Bakken crude was predicted to oil further downstream, which took more time and resulted in more surface area with oil. The additional time for downstream transport and oiled surface area therefore allowed for more oil to evaporate to the atmosphere.

6.1.5.2.2 Trajectory and Fate Results for Average River Flow (Summer-Fall)

Under average river flow, Bakken crude was predicted to be transported approximately 22.8 miles (36.7 km) downstream, over the full 24-hour modeled period. After this distance, the oil would have been transported to the north to a point between the entry of the Two Rivers and Pembina, close to 101st Street NE in North Dakota. Approximately 17% of the Bakken crude was predicted to oil the shorelines of the Red River, 46.2% to have evaporated to the atmosphere, and 36.9% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude oil on the river surface after 24 hours would be expected to continue downstream, weathering and oiling shorelines until all of the oil was removed from the water surface.

The Bakken crude was predicted to be transported 17.5 miles (28.2 km) less under average river flow conditions, when compared to the higher river flow conditions. The lower river velocities of the average river flow condition prevented the oil from being transported as far within the 24 hour simulation period. The Bakken crude evaporated more under the average flow conditions (46.2%) than the high river flow condition (41.4%) partially due to the higher air temperatures.

Additionally, under the average river flow condition the oil was transported downstream for the full 24 hours, as opposed to the high river flow condition that ends after 18.5 hours. This longer time allowed the Bakken crude to evaporate more before the end of the simulation.

When compared to the CLB under average river flow conditions, the Bakken crude was transported 3.6 miles (5.8 km) further downstream before reading the 24 hour model limit. Additionally 36.9% of the Bakken crude was still remaining on the river surface at the end of the simulation. The Bakken crude was able to travel further downstream, under the same river velocities, due to the lower shoreline oil retention value for Bakken, when compared to CLB.

6.1.5.2.3 Trajectory and Fate Results for Low River Flow (Winter)

Under low river flow, Bakken crude was predicted to be transported approximately 16.0 miles (25.7 km) downstream, over the full 24-hour modeled period. Approximately 10.3% of the Bakken crude was predicted to oil shorelines of the Red River, and the remaining 89.7% to remain in the river below the ice at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude in the river after 24 hours would be expected to continue downstream, oiling shorelines until all the oil was removed from the water surface.

Relative to the high river flow condition, the Bakken crude was predicted to be transported 24.3 miles (39.1 km) fewer downstream. Relative to the average river flow conditions, the Bakken crude is predicted to be transported 6.8 miles (10.9 km) fewer downstream. Under low river flow conditions, the shore types were assumed to be the same as the average flow condition. With the oil being transported at a slow velocity, the 24 hour time limit was reached, resulting in a shorter distance oiled than that average river flow condition. With the Bakken crude below the ice of the river, no oil was allowed to evaporate from the surface.

When compared to the CLWB under low river flow conditions, 55.8% less of the Bakken crude remained on the river shorelines under the ice. This was due to the differences in the shoreline oil retention between the two oils. For this reason, 55.8% more oil was able to be transported downstream under the ice.

6.1.2 Summary of OILMAP Land Trajectory and Fate Results

The most important factor driving the transport of released oil in a river is the volume (discharge) of water and resulting velocity moving downstream. Typically, higher flow rates result in further downstream transport and more extensive shoreline oiling (Table 6-1). Based upon the river velocities at each location, the furthest downstream release extent is expected for the Red River. In some cases, changing shoreline types with the range of seasons did result in further downstream transport under low or average river flow conditions, when compared to high river flow conditions.

Table 6-1 Downstream Distance (miles) Maximum Oil Flow at the End of the Simulations

Location	Oil Type	Season / River Flow		
		Low	Average	High
Mosquito Creek	Bakken Crude	0.8	9.7	10.5
	Cold Lake Blend	0.8	3.5	3.5
Mississippi River at Ball Club (assumed grass shore type)	Bakken Crude	6.5 (6.5)	5.7 (15.9)	6.4 (23.0)
	Cold Lake Blend	1.3 (6.5)	1.3 (8.0)	1.3 (8.1)
Sandy River	Bakken Crude	6.0	9.1	12.2
	Cold Lake Blend	6.0	7.8	8.1
Shell River to Twin Lakes	Bakken Crude	1.5	13.9	21.9
	Cold Lake Blend	0.8	3.7	3.7
Red River	Bakken Crude	16.0	22.8	40.3
	Cold Lake Blend	16.0	19.2	10.5

Under winter conditions, snow and ice may significantly affect the predicted transport and fate of oil. Snow has the potential to slow downslope oil transport, with high absorbency. For releases at Mosquito Creek, snow cover under winter conditions prevented the releases from entering the water course, which did occur during summer and spring conditions. Ice has the potential to prevent oil from entering a waterway if the oil is released on land. However, if oil were to be released under ice, the in-water effects could be substantially greater due to the "capping" of the river, which would prevent evaporative losses and result in substantially more dissolution of hydrocarbons into the water column.

Two main differences between oil fates were observed when the CLB results were compared to those of the Bakken crude oil releases. Of primary importance, CLWB and CLSB have a higher density and viscosity, relative to the Bakken. This affects its shoreline oil retention values and results in more extensive shoreline oiling (thicker) for CLWB and CLSB, relative to the Bakken. In most scenarios, this results in further downstream transport of Bakken. In the event of an actual release, the downstream extents of CLSB and Bakken Crude may be more similar, and the effects of CLSB may extend farther downstream than presented, with patchy coverage. This is most important under high and average flow conditions, where the transport is directly limited by shoreline retention, as opposed to the downstream extent in low flow conditions predominantly being controlled by the low velocity. Of secondary importance is the volatile content, which controls the amount and rate of evaporation. More Bakken is expected to evaporate and at a higher rate, compared to CLWB and CLSB.

OILMAP Land is not able to provide detailed predictions of 3-D oil fate and transport. This includes processes such as entrainment of oil into the water column, dissolution of soluble fractions of hydrocarbons, emulsion formation, potential biological effects from exposure to oil, and other complex interactions. While these processes were not modeled for these five sites, they were modeled at the Mississippi River at Palisade and Little Falls using the SIMAP model application. These results are discussed in Section 6.2.

6.2 DESCRIPTION OF SIMAP MODEL OUTPUTS

This section provides modeled predictions of the expected trajectory and fate of hypothetical releases of two crude oils at two hypothetical releases located along the Mississippi River at Little Falls and Palisade and under multiple environmental conditions. Trajectory and fate results are depicted for each combination of season (high, average, and low river flow) for releases of both CLB and Bakken Crude oil types. A set of figures is provided for each of the twelve modeled scenarios.

The hydrocarbon trajectory provides a history of oil transport throughout the modeled domain in both time and space. Components of the oil are tracked as entrained droplets of oil within the water column, dissolved aromatics, floating surface oil, stranded oil on shorelines, oil in the sediment, and that which evaporated or decayed. The following points describe the types of figures produced through the modeling process and the information portrayed. Summary figures of trajectory and fate are provided for each location, season, and release volume. Mass balance information at the end of the 24-hour simulation is provided in tables for each of the release scenarios in terms of percent of oil spilled.

1. **Mass Balance Plots**: Provide an estimate of the weathering and fate of oil for a specific run for the entire model duration as a fraction of the oil spilled up to that point. Components of the oil tracked over time include the amount of oil on the water surface, the total entrained hydrocarbons in the water column, the amount of oil on shore, the oil evaporated into the atmosphere, the oil in sediments, and the amount of oil that has decayed (accounts for both photo-oxidation and biodegradation).
2. **Hydrocarbon Trajectory Maps:** Show the history of each individual particle of oil throughout the modeled domain in both time and space. Components of the oil were tracked as entrained droplets of oil, dissolved aromatic constituents, floating surface oil, and stranded shoreline oil. Trajectory maps are provided for 6, 12, and 24 hours after the initial release.
3. **Surface Oil Thickness Maps:** Depict the footprint of maximum floating surface oil and the associated oil thicknesses (mm) of each individual spill simulation at 24 hours.
4. **Water Column Concentration Maps:** Depict the footprint of the vertical maximum water column concentration of dissolved aromatics (µg/l or ppb) at 24 hours for each individual spill simulation. Dissolved aromatics are the portion of the oil having the greatest potential to affect water column biota, and the footprints were typically smaller than the extent of total oil contamination in the water column. Water column contamination figures show only concentrations ≥ 1 ppb. Concentrations below 1 ppb are considered low and result in little water column impact.

5. **Shoreline and Sediment Impact Maps:** Depict the total mass of oil deposited onto the shoreline and on sediments. Note that 1 µm thickness is roughly equivalent to 1 g/m^2.

6.2.1 Unmitigated Hypothetical Release Case 6—Mississippi River at Palisade

The Mississippi River passes to the south and east of the town of Palisade, Minnesota. The pipeline route crosses the Mississippi River 1.08 miles (1.74 km) to the south-south west of Palisade and to the southern edge of Great River Road (Rt. 10). At this location the Mississippi River flows to the south and west through a low energy and sinuous channel that passes through mainly agricultural lands with forested banks. Approximately 11 miles (17.7 km) to the south west of the hypothetical release location, the main stem of the Mississippi River continues to the south and west before continuing to the north and then west towards Wolford. At this point, the Aitkin Low Head Dam may be found with its flood diversion channel that flows due west along Great River Road (Rt. 21), 400th Lane, and then 400th St (Rt. 11) before rejoining the main stem of the Mississippi River. This flood diversion channel was only hydraulically connected to the Mississippi River during the modeled high river flow conditions. The width of the Mississippi River averages approximately 200-250 ft (61-76 m) in this area. Expected environmental and flow conditions used in modeling for the Mississippi River at Palisades are provided in Figure 5-5 and Tables 5-13 and 5-14.

6.2.1.1 Cold Lake Blend Scenarios

The Mississippi River at Palisade scenarios represent a low energy environment for the SIMAP analysis. Hypothetical releases of CLB at the Mississippi River at Palisade under high flow conditions resulted in oil that was transported downstream approximately 4, 8, and 17.5 miles (6.4, 12.8, and 28.2 km) after 6, 12, and 24 hours, respectively (Figure 6-15, Figure 6-16, and Figure 6-17). Under average river flow conditions, the release had a maximum extent of approximately 14 miles (22.5 km) after 24 hours (Figure 6-22, Figure 6-23, and Figure 6-24). During low river flows, the majority of the release was trapped at the ice-water interface within 1.5 miles (2.4 km) of the hypothetical release point, while the maximal extent of oil was approximately 2.5 miles (4.0 km) (Figure 6-37, Figure 6-38, and Figure 6-39). Table 6-2 provides a summary of the mass balance information at the end of the 24-hour simulation, while Figure 6-13 provides the furthest predicted downstream extent of whole oil.

Table 6-2 Summary of the CLB (CLSB or CLWB) Mass Balance Information at the Mississippi River at Palisade Release Location at the End of the 24-Hour Simulation [1]

Figure 6-13 Predicted Downstream Transport of CLB Oil at the Mississippi River at Palisade Release Location

During high and average river flow conditions, the relatively calm waters (i.e., not a lot of surface breaking disturbances) of the Mississippi River near Palisade did not entrain oil into the water column. Rather, these releases were typified by large amounts of floating oil, which formed thick surface oil slicks over much of the river (Figure 6-18 and Figure 6-25). At the end of the 24-hour simulation, floating oil thicknesses greater than 1 mm (heavy black oil) remained on the water surface. There was no floating surface oil less than 0.01 mm thick (dark brown oil). The presence of extensive surface slicks resulted in significant evaporation, with approximately 20% of the total release ending up in the atmosphere (Table 6-3).

Extensive shoreline oiling and limited sediment oiling was observed for approximately 17.5 miles (28.2 km) of the river below the release location under high river flow conditions (

Figure 6-20) and 14.5 miles (23.3 km) under average river flow conditions (Figure 6-27).

Surface oil evaporated rapidly over the 24-hour simulation (Figure 6-14, Figure 6-21, and Table 6-2). This natural weathering resulted in increased viscosity of the CLSB, which further reduced

the likelihood of potential entrainment into the water column. Because of this, total hydrocarbon concentrations (i.e. whole oil in the water column) were extremely low due to the oil remaining on the surface and not entrained within the water column.

The maximum concentration of dissolved aromatics was greater than 5,000 ppb in small regions within the spill extent; however, most of the dissolved aromatic concentrations were between 1 and 100 ppb (Figure 6-19). Of the oil that made its way into the water column, a portion did interact with SPM (also referred to as Total Suspended Solids or TSS). THCs on the sediment were generally less than 0.01 g/m^2, with small segments as high as 1 g/m2 (

Figure 6-20 and Figure 6-27). The concentrations on the shore were primarily greater than 500 g/m^2. The highest sediment concentrations were predicted for the high river flow scenario due to the higher concentration of TSS in the water column.

For the low river flow scenario, the hydrocarbon trajectory at the end of the 24-hour simulation extended 2.5 miles (4 km) from the spill location (Figure 6-31). Under low river flow conditions the

100% surface coverage of ice kept the entrained oil in the water column at the ice/water interface (97.7%) (Figure 6-31 and Figure 6-32). Patchy oiling along river banks was observed, however the majority of the oil remained trapped under the ice (Table 6-2). Concentrations on the shore were primarily greater than 500 g/m^2, with some segments less than 1 g/m^2 (Figure 6-34). A large portion of the soluble portion of the CLWB dissolved into the water column and was transported downstream, resulting in elevated dissolved aromatic concentrations within the water column (Figure 6-33). Dissolved aromatic components traveled downstream from the initial spill location with maximum concentrations greater than 5,000 ppb in regions within the spill extent (Figure 6-33). Much larger portions of the river are predicted to experience dissolved aromatic concentrations in excess of 5,000 ppb, when compared to average or low flow scenarios. At the end of the 24-hour simulation, floating oil greater than 1 mm thick (heavy black oil) remained under the ice (Figure 6-32). There was no floating surface oil less than 0.1 mm thick (black oil). Small amounts of sediment oiling did extend down to approximately 2.5 miles (4 km) (Figure 6-34), although the total hydrocarbon concentrations on the sediment were generally less than 0.01 g/m^2. There was very little decay from any of the three hypothetical releases within the timeframe modeled.

6.2.1.2 Bakken Crude Scenarios

The Mississippi River at Palisade scenarios represent a low energy environment for the SIMAP analysis. Hypothetical releases of Bakken crude at the Mississippi River at Palisade resulted in the same downstream transport as the CLB. This was due to the released oil experiencing the same environmental forcing. Under high flow conditions predicted downstream transport was 4, 8, and 17.5 miles (6.4, 12.8, and 28.2 km) downstream after 6, 12, and 24 hours, respectively (Figure 6-37, Figure 6-38, and Figure 6-39). Under average river flow conditions, the release had a maximum extent of approximately 14.3 miles (23.0 km) after 24 hours (Figure 6-44, Figure 6-45, and Figure 6-46). During low river flows, the majority of the release was trapped at the ice-water interface within 1.5 miles (2.4 km) of the hypothetical release point, while the maximal extent of oil was approximately 2.8 miles (4.51 km) (Figure 6-51, Figure 6-52, Figure 6-53). Any slight differences between the downstream distance of Bakken versus CLB scenarios is the result of the effects of randomized dispersion. This does not significantly affect the downstream distance, but rather the exact location of each Lagrangian element (i.e., discretized spill) at each time step. Table 6-3 provides a summary of the mass balance information at the end of the 24-hour simulation, while Figure 6-35 provides the furthest predicted downstream extent of whole oil.

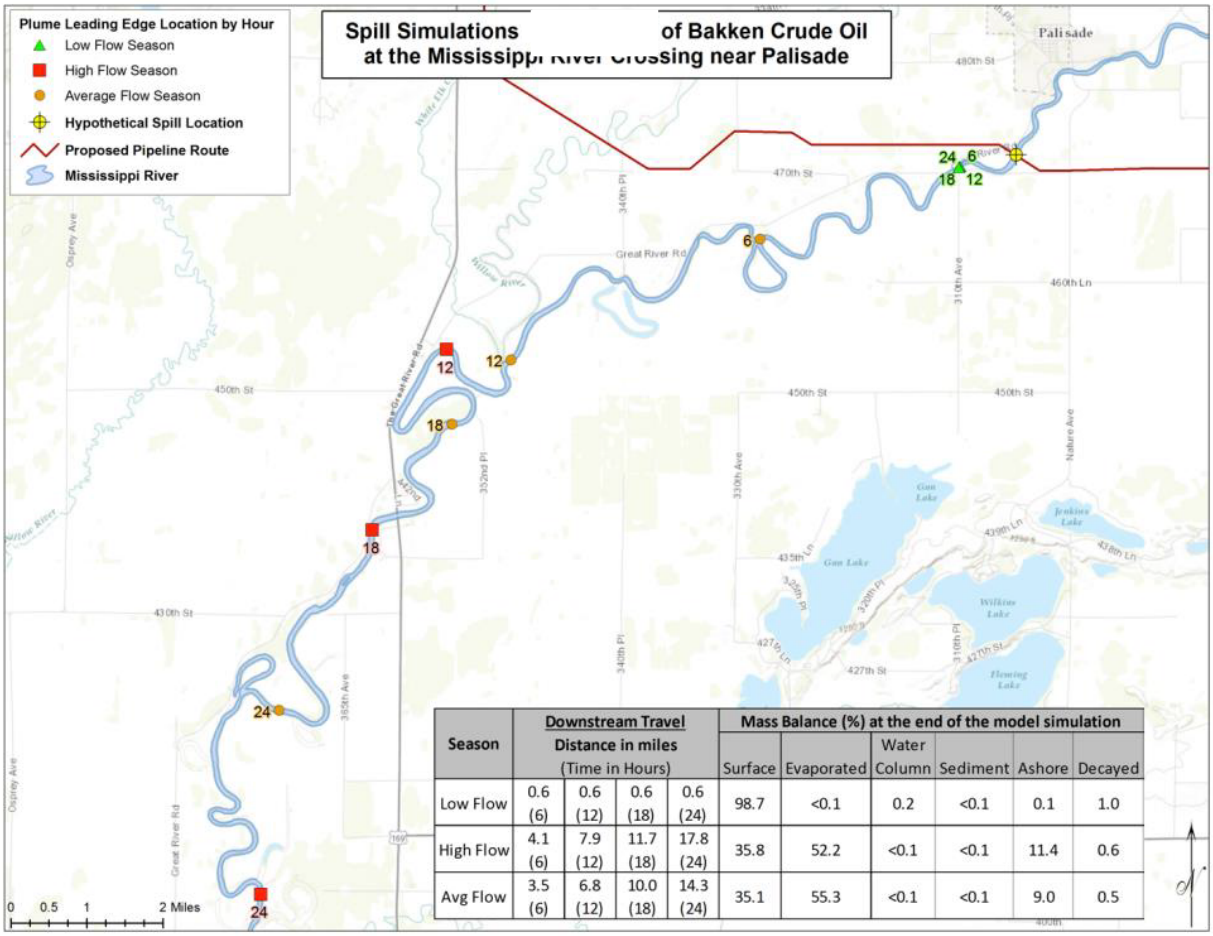

Table 6-3 Summary of the Bakken Crude (BAK) Mass Balance Information at the Mississippi River at Palisade Release Location at the End of the 24-Hour Simulation [1]

Scenario	Surface (%)	Evaporated (%)	Water Column (%)	Sediment (%)	Ashore (%)	Decayed (%)

Figure 6-35 Predicted Downstream Transport of Bakken Crude oil at the Mississippi River at Palisade Release Location

During high and average river flow conditions, the relatively calm waters (i.e., not a lot of surface breaking disturbances) of the Mississippi River near Palisade did not entrain oil into the water column. Rather, these releases were typified by large amounts of floating oil, which formed thick surface oil slicks over much of the river (Figure 6-40 and Figure 6-47). At the end of the 24-hour simulation, floating oil thicknesses greater than 1 mm (heavy black oil) remained on the water surface. There was no floating surface oil less than 0.01 mm thick (dark brown sheen).

Extensive shoreline oiling and limited sediment oiling was observed for approximately 17.5 miles (28.2 km) of the river below the release location under high river flow conditions (Figure 6-42) and 19.2 miles (30.9 km) under average river flow conditions (Figure 6-49).

Surface oil evaporated rapidly over the 24-hour simulation (Figure 6-36, Figure 6-43, and Table 6-3). As Bakken is a much lighter crude oil with a higher volatile content than CLB, greater than 50% is predicted to evaporate over 24 hours (Table 6-3), nearly 2.5 times that of the CLB (Table 6-2). There was a low potential for Bakken entrainment into the water column due to the low winds, which did not cause surface breaking waves, and the lack of rapids, riffles, and waterfalls in this area of the Mississippi. Because of this, total hydrocarbon concentrations (i.e. whole oil in the water column) were extremely low due to the oil remaining on the surface of the water and not entrained within the water column.

The maximum concentration of dissolved aromatics was greater than 5,000 ppb in small regions within the spill extent; however, most of the dissolved aromatic concentrations were between 10 and 50 ppb (Figure 6-41 and Figure 6-48). Concentrations were higher for Bakken scenarios, when compared to the CLB scenarios, due to the higher aromatic content of the lighter Bakken oil. Of the oil that made its way into the water column, a portion did interact with SPM. Total hydrocarbon concentrations on the sediment were generally less than 0.01 g/m^2, with small segments as high as 0.5 g/m^2 (Figure 6-42 and Figure 6-49). Concentrations on the shore were generally between 100-500 g/m^2, which was lower than the CLB scenario. This is due to the lower viscosity of the Bakken, which results in thinner oiling of shorelines. Additionally, less oil would be expected to reach sediments in the Bakken releases, when compared to the CLB. The highest sediment concentrations were predicted for the high river flow scenario due to the higher concentration of TSS in the water column.

For the low river flow scenario, the hydrocarbon trajectory at the end of the 24-hour simulation extended 0.5 miles (0.8 km) from the spill location (Figure 6-53). This distance was only approximately one-third that of the CLB and was the result of the difference in oil density. Bakken is a much less dense oil and would rise through the water column more rapidly than the CLB. Because the oil spends less time in the water column, before it rises to the surface and sticks to the underside of the ice, it is transported less distance downstream. Under low river flow conditions the 100% surface coverage of ice kept the entrained oil in the water column at the ice/water interface (98.7%) (Figure 6-50 and Figure 6-54). Patchy oiling along river banks was observed, however the majority of the oil remained trapped under the ice (Table 6-2). Slightly lower amounts of oil were predicted along shorelines for Bakken, compared to CLB. Concentrations on the shore were primarily greater than 500 g/m^2 within the vicinity of the release location, with some segments downstream with concentrations less than 1 g/m^2 (Figure 6-56). A larger portion of the soluble portion of the Bakken dissolved into the water column and was transported downstream, resulting in elevated dissolved aromatic concentrations within the water column (Figure 6-55). Dissolved aromatic components traveled downstream from the initial spill location with maximum concentrations greater than 5,000 ppb in regions within the spill extent (Figure 6-55). Much larger portions of the river are predicted to experience dissolved aromatic concentrations in excess of 5,000 ppb, when compared to average or low flow scenarios. At the end of the 24-hour simulation, floating oil greater than 1 mm thick (heavy black oil) remained under the ice (Figure 6-54). There was no floating surface oil less than 0.1 mm thick (black oil). Small amounts of sediment oiling did extended down to approximately 1.2 miles (1.9

km) (Figure 6-56), although the total hydrocarbon concentrations on the sediment were generally less than 0.01 g/m^2. There was very little decay from any of the three hypothetical releases within the timeframe modeled.

6.2.2 Unmitigated Hypothetical Release Case 7—Mississippi River at Little Falls

The pipeline route crosses the Mississippi River approximately 4.89 miles (7.87 km) to the north of Little Falls, Minnesota, at Island Forty Eight. At this location the river is much larger, with a width of approximately 820 ft (250 m), as it travels through a relatively straight channel to the south. There are a number of wooded islands in this portion of the Mississippi River that range in size from a few hundred feet (100 m) to half a mile (0.8 km). Rather than being sinuous and marshy, like previously modeled reaches, this wide channel is lined with forested banks, passing through agricultural lands and by larger cities such as Little Falls and St. Cloud. Approximately 5.2 miles downstream of the hypothetical release location, the Mississippi River passes over the Little Falls Dam, a hydroelectric dam that is approximately 24 ft (7.3 m) tall. This concrete dam has a number of chutes or spillways that can create a tremendous amount of turbulence as water passes over top. Another 10 miles downstream, the Blanchard Dam may be found to the east of Great River Road (Rt. 24), west of Rt. 305, and at the Soo Line All-Terrain Vehicle Trail. This concrete dam is the tallest dam on the Mississippi at 46 ft (14.0 m) tall and is another hydroelectric station. The large amounts of turbulence at the dams and at the rapids downstream were modeled. Expected environmental and flow conditions used in modeling for the Mississippi River at Palisades are provided in Figures 5-41 to 5-43, and Tables 5-13 and 5-14.

6.2.2.1 Cold Lake Blend Scenarios

The Mississippi River at Little Falls scenarios represent a high energy environment with several waterfalls for the SIMAP analysis. Hypothetical releases of Cold Lake under high flow conditions resulted in oil that was transported downstream 10, 17, and 30 miles (16.1, 27.4, and 48.2 km) after 6, 12, and 24 hours, respectively (Figure 6-59, Figure 6-60, and Figure 6-61). Under average river flow conditions, the release had a maximum extent of approximately 30 miles (48.3 km) after 24 hours (Figure 6-69). During low river flows, the majority of the release was trapped at the ice-water interface within 4.0 miles (6.4 km) of the hypothetical release point, while the maximal extent of oil was approximately 5.5 miles (8.9 km) (Figure 6-76). Table 6-4 provides a summary of the mass balance information at the end of the 24-hour simulations, while Figure 6-57 provides the furthest predicted downstream extent of whole oil.

Figure 6-57 Predicted Downstream Transport of CLB Oil at the Mississippi River at Little Falls Release Location

During high and average river flow conditions, the relatively calm waters upstream and downstream of the Little Falls Dam and Blanchard Dam resulted in large amounts of floating oil, which formed thick surface slicks over much of the river (Figure 6-62 and Figure 6-70). Surface slicks for the Mississippi River at Little Falls were in general, thinner and more extensive than those of the Mississippi River at Palisade. This was the result of more rapid and turbulent river flow at Little Falls. At the end of the 24-hour simulation, floating oil thicknesses between 0.1-1 mm (heavy black oil) remained on the water surface, with localized areas exceeding 1 mm. There was no floating surface oil less than 0.01 mm thick (dark brown sheen). The presence of extensive surface slicks resulted in significant evaporation, with approximately 20% of the total release ending up in the atmosphere (Table 6-4).

Extensive shoreline oiling was observed for approximately 29 miles (46.7 km) of the river below the release location under high river flow conditions (Figure 6-64) and average river flow conditions (Figure 6-72). The concentrations of CLB on the shore were primarily greater than 500 g/m^2, with some segments between 100 and 500 g/m^2.

Mass balance information for the high and average river flow conditions, depict two points of interest approximately 0.2 and 0.6 days (4.8 and 14.4 hours) into the average and high river flow releases (Figure 6-58 and Figure 6-66). Two "humps" or increases in the mass balance were identified representing a large amount entrained oil. These increases in entrained oil were observed, as the oil passed over the Little Falls Dam and then the Blanchard Dam, along with the associated rapids downstream (Figure 6-61 and Figure 6-69). Entrained oil droplets in the water column then rose to the surface over subsequent quiescent reaches of the river, where entrained oil rose back to the surface. A depiction of the dissolved aromatic concentration and total hydrocarbon concentration within the water column at the Little Falls Dam is presented at a time when a portion of the release was above and below the dam (Figure 6-65). Above the dam, note that there are no observed total hydrocarbon concentrations, the oil is floating on the water surface. A portion of this surface oil is dissolving into the surface water column (100 ppb), but is mainly evaporating. However, immediately downstream of the dam, the total hydrocarbon concentration increases (greater than 25 ppm) and dissolved aromatic concentration within the water column increases (100–1,000 ppb), as the whole oil droplets are now in the water column where the soluble portions dissolve into the water. The total hydrocarbon concentration decreases in the water column as distance downstream of the dam increases due to the buoyant rise of whole oil droplets to the surface in the relatively quiescent waters downstream.

When oil is mixed through the water column by turbulent mixing processes such as waterfalls at dams, there is a high potential for oil-SPM interactions with the possibility of "sinking oil." Substantial oiling of the sediment was observed in both the high and average river flow scenarios, with concentrations between 0.01–0.5 g/m^2 along approximately 24 and 30 miles (38.6 and 48.2 km) of river bottom below Little Falls Dam (Figure 6-64 and Figure 6-72). In patchy and localized portions of the Mississippi River downstream of the waterfalls, sediment concentrations are predicted to exceed 500 g/m^2. However, the majority of sediment oiling is

much lower in concentration over the larger area with any amount of potential oil on the sediments. Between 0.3 and 0.5% of the CLB release is predicted to be found in the sediments under ice-free conditions. Higher sediment oiling is predicted under high river flow rates due to the increased turbulence and higher suspended sediment load within the water column. The lowest sediment concentrations and smallest areas with sediment oil were predicted for low flow conditions (Figure 6-78).

The maximum concentration of dissolved aromatics was greater than 5,000 ppb in small regions within the spill extent; however, most of the dissolved aromatic concentrations ranged between 25 and 150 ppb (Figure 6-63 and Figure 6-71). The enhanced dissolved aromatic concentrations were due to dissolution of the soluble portion of the CLWB into the water column. While this may be expected to cause higher concentrations (as observed in the Palisade case), it is important to consider that in the Little Falls scenarios, vertical mixing results in more uniform concentrations throughout the water column, as opposed to a localized or thin layer with elevated concentrations at the surface for the scenarios at Palisade.

For the low river flow scenario, the hydrocarbon trajectory at the end of the 24-hour simulation extended 4.0 miles (6.4 km) from the hypothetical release location, while the maximal extent of oil was approximately 5.5 miles (8.9 km) downstream (Figure 6-77). The downstream extent is further in this scenario than for those at Palisade due to the higher river velocity which transports oil more rapidly as it rises through the water column. In addition the water column is deeper at this release point, relative to Palisade. Finally, the CLWB has a higher density than the Bakken and therefore rises at a slower rate, being transported further downstream before sticking to the underside of the ice. Under low river flow conditions the 100% surface coverage of ice kept the entrained oil in the water column at the ice/water interface (97.0%) (Figure 6-73 and Figure 6-76). Patchy shoreline oiling along river banks was observed between miles 1 and 2 (1.6 and 3.2 km) downstream from the release point. However, the majority of the oil remained trapped under the ice (Table 6-4). Concentrations on the shore were predominantly 1–100 g/m^2, with some segments of the shoreline with values between 100–500 g/m^2 and others exceeding 500 g/m^2 (Figure 6-79).

The soluble portion of the CLWB would dissolve into the water column and be transported downstream, resulting in elevated dissolved aromatic concentrations within the water column (Figure 6-78). Dissolved aromatic components traveled downstream from the initial release location with maximum concentrations greater than 5,000 ppb in the region between 1–3 miles (1.6 to 4.8 km) of release location at hour 24.

At the end of the 24-hour simulation, floating oil under the ice had a thickness greater than 1 mm thick (heavy black oil) (Figure 6-77). There was no floating surface oil less than 0.01 mm thick (dark brown sheen). Small amounts of sediment oiling did extend down to approximately 8.5 miles (13.7 km) (Figure 6-79), although the total hydrocarbon concentrations on the sediment were generally less than 0.01 g/m^2 due to the small amount of SPM in the water column.

There was very little decay from any of the three hypothetical releases within the timeframe modeled (Table 6-4).

6.2.2.2 Bakken Crude Scenarios

The Mississippi River at Little Falls scenarios represent a high energy environment with several waterfalls for the SIMAP analysis. Hypothetical releases of at the Mississippi River at Little Falls resulted in the same downstream transport as the CLB. This was due to the released oil experiencing the same environmental forcing. Under high flow conditions oil was transported downstream 9.5, 17, and 31 miles (15.3, 27.4, and 49.9 km) after 6, 12, and 24 hours, respectively (Figure 6-82, Figure 6-83, and Figure 6-84). Under average river flow conditions, the release had a maximum extent of approximately 30 miles (48.3 km) after 24 hours (Figure 6-91). During low river flows, the majority of the release was trapped at the ice-water interface within 1.5 miles (2.4 km) of the hypothetical release point, while the maximal extent of oil was approximately 2.0 miles (3.2 km) (Figure 6-98). Table 6-5 provides a summary of the mass balance information at the end of the 24-hour simulations, while Figure 6-80 provides the furthest predicted downstream extent of whole oil.

Figure 6-80 Predicted Downstream Transport of Bakken Crude Oil at the Mississippi River at Little Falls Release Location

During high and average river flow conditions, the relatively calm waters upstream and downstream of the Little Falls Dam and Blanchard Dam resulted in large amounts of floating oil, which formed extensive surface slicks over much of the river (Figure 6-85 and Figure 6-92). Surface slicks for the Mississippi River at Little Falls were in general thinner and more extensive than those of the Mississippi River at Palisade. This was the result of more rapid and turbulent river flow at Little Falls. Additionally, for Bakken crude, slicks were thinner than CLB. At the end of the 24-hour simulation, floating oil thicknesses between 0.01 and 1 mm (dark brown sheen and black oil) remained on the water surface. There were some areas of river with floating surface oil less than 0.001 mm thick (representing colorless and silver sheens and rainbow sheens). The presence of extensive surface slicks resulted in significant evaporation, with approximately 50% of the total release ending up in the atmosphere (Table 6-5).

Extensive shoreline oiling was observed for approximately 30 miles (48.3 km) of the river below the release location under high river flow conditions (Figure 6-87) and 29 miles (46.7 km) under average river flow conditions (Figure 6-94). The concentrations of Bakken on the shore were generally 100–500 g/m^2 with nearly equal lengths of shoreline exceeding 500 g/m^2. In general, Bakken resulted in less extensive shoreline oiling than the CLB.

Similar to the CLB scenarios, Bakken crude behaved similarly over water falls. A large portion of the released oil would be entrained into the water column at both Little Falls Dam and Blanchard Dam. This would result in large increases in the THC concentration within the water column and would result in enhancements in the dissolved aromatic concentration (Figure 6-81 and Figure 6-88). Slightly lower amounts of entrained oil are found in the water column and surface oil returns more rapidly downstream of dams in the Bakken release. This is the result of the Bakken crude being less dense than CLB, which results in a larger buoyant force and a more rapid rise in velocity of Bakken oil droplets.

Oil-SPM interactions were observed with the Bakken crude oil as well, which resulted in the possibility of "sinking oil" (Figure 6-87 and Figure 6-94). Approximately 30 miles (48.3 km) of river bottom were predicted to have sediment oiling less than 0.01 g/m^2, with some localized areas experiencing 0.01–0.5 g/m^2. Below Blanchard Dam, after the second waterfall entrained oil and further mixing with SPM, some patchy and localized portions of the river bottom may have sediment concentrations between 1 and 10 g/m^2 with values as high as 10–50 g/m^2 in very small areas. In general, Bakken was more easily entrained into the water column due to its lower viscosity. However, the overall quantity of oil interacting with SPM was lower than the CLB. Less than 0.1% of the release is predicted to be found in the sediments under ice-free conditions. This is over six times lower than the predictions for CLB. Higher sediment oiling is predicted under high river flow rates due to the increased turbulence and higher suspended sediment load within the water column. The lowest sediment concentrations and smallest areas with sediment oil were predicted for low flow conditions (Figure 6-101).

The maximum concentration of dissolved aromatics was greater than 500 ppb in small regions within the spill extent; however, most of the dissolved aromatic concentrations ranged between

25 and 100 ppb (Figure 6-87 and Figure 6-94). The enhanced dissolved aromatic concentrations were due to dissolution of the soluble portion of the Bakken into the water column. While this may be expected to cause higher concentrations (as observed in the Palisade case), it is important to consider that in the Little Falls scenarios, vertical mixing resulted in more uniform concentrations throughout the water column, as opposed to a localized or thin layer with elevated concentrations at the surface for the scenarios at Palisade. Although Bakken has a higher aromatic content than Bakken, concentrations were slightly lower for Bakken than the CLB as entrained droplets rose more quickly through the water column downstream of the dams, where they formed surface slicks and evaporated more completely.

For the low river flow scenario, the hydrocarbon trajectory at the end of the 24-hour simulation extended 1.5 miles (2.4 km) of the hypothetical release point, while the maximal extent of oil was approximately 2.0 miles (3.2 km) (Figure 6-98). The downstream extent is further in this scenario than for those at Palisade due to the higher river velocity, which transported oil more rapidly as it rose through the water column. In addition the water column is deeper at this release point, relative to Palisade. However, the extent was smaller than that of the CLWB, due to the lower density and more rapid rise rate through the water column, before sticking to the underside of the ice. Under low river flow conditions the 100% surface coverage of ice kept the entrained oil in the water column at the ice/water interface (97.4%) (Figure 6-95 and Figure 6-99). Extremely patchy oiling along river banks was observed downstream from the release point, with concentrations on the shoreline less than 1 g/m^2 (Figure 6-101). Extremely small amounts of oil may be found on the sediments, with most concentrations falling less than 0.01 g/m^2.

Large portions of the soluble portion of the Bakken dissolved into the water column and was transported downstream, resulting in elevated dissolved aromatic concentrations within the water column (Figure 6-100). Dissolved aromatic components traveled downstream from the initial spill location with maximum concentrations greater than 5,000 ppb directly under the oil trapped under the ice. Much larger portions of the river are predicted to experience dissolved aromatic concentrations in excess of 5,000 ppb, when compared to average or low flow scenarios.

At the end of the 24-hour simulation, floating oil under the ice had a thickness greater than 1 mm thick (heavy black oil) (Figure 6-99). There was no floating surface oil less than 0.1 mm thick (black oil). Small amounts of sediment oiling did extend dowstream, although the total hydrocarbon concentrations on the sediment were generally less than 0.01 g/m^2 due to the small amount of SPM in the water column.

There was very little decay from any of the three hypothetical releases within the timeframe modeled (Table 6-5).

6.2.3 Summary of SIMAP Trajectory and Fate Results

In general, higher river flow resulted in further potential to oil regions downstream from the release location (Table 6-6). Modeled releases in the quiescent waters of the Mississippi River at Palisade resulted in large surface oil slicks, which resulted in large evaporative losses. Approximately 20% of the CLB and approximately 50% of the Bakken evaporated under high and average river flow conditions. Extensive shoreline oiling was also observed, with thicker shoreline oiling greater than 500 g/m^2 in CLSB scenarios, and 100–500 g/m^2 in Bakken release scenarios. Dissolved aromatic concentrations did exceed 5,000 ppb in both scenarios, due to dissolution of oil into the waters immediately below the surface slick. In general, dissolved aromatic concentrations were relatively patchy and generally lower than 100 ppb for both oil types. A small amount of sediment oiling (generally less than 0.01 g/m^2) was possible for releases at Palisade, with the highest potential under high flow conditions with larger concentrations of SPM within the water column. CLB had a higher potential to make its way to sediments, when compared to Bakken.

Table 6-6 Downstream Distance (miles) Maximum Oil Flow at the End of the Simulations

Location	Oil Type	Season / River Flow		
		Low	Average	High
Mosquito Creek	Bakken Crude	0.8	9.7	10.5
	Cold Lake Blend	0.8	3.5	3.5
Mississippi River at Ball Club (assumed grass shore type)	Bakken Crude	6.5 (6.5)	5.7 (15.9)	6.4 (23.0)
	Cold Lake Blend	1.3 (6.5)	1.3 (8.0)	1.3 (8.1)
Sandy River	Bakken Crude	6.0	9.1	12.2
	Cold Lake Blend	6.0	7.8	8.1
Shell River to Twin Lakes	Bakken Crude	1.5	13.9	21.9
	Cold Lake Blend	0.8	3.7	3.7
Red River	Bakken Crude	16.0	22.8	40.3
	Cold Lake Blend	16.0	19.2	10.5
Mississippi River at Palisade	Bakken Crude	0.6	14.3	17.8
	Cold Lake Blend	2.4	14.0	17.9
Mississippi River at Little Falls	Bakken Crude	2.1	31.2	31.0
	Cold Lake Blend	5.6	29.9	32.3

Modeled releases in the more turbulent waters of the Mississippi River at Little Falls still had large surface oil slicks, which resulted in large evaporative losses. Similar to the Palisades scenarios, under high and average river flow rates, approximately 20% of the CLB and approximately 50% of the Bakken evaporated. Extensive shoreline oiling was also observed, with thicker shoreline oiling greater than 500 g/m^2 in CLSB scenarios, and 100–500 g/m^2 in Bakken release scenarios. Dissolved aromatic concentrations did exceed 5,000 ppb in both scenarios, due to dissolution of oil into the waters immediately below the surface slick. In general, dissolved aromatic concentrations were relatively patchy and generally lower than 100 ppb for both oil types. The presence of the Little Falls Dam and Blanchard Dam resulted in large amounts of oil being entrained into the water column at the waterfalls and sections of rapids. Hydrocarbon concentrations within the water column were typically much higher after the dams, with greater than 25 ppm for THC and 250-500 ppb for dissolved aromatics. In the quiescent waters downstream, the oil resurfaced and once again formed surface slicks.

Due to the large amount of vertical mixing and the presence of suspended sediments, particularly under high flow conditions, there was a substantially higher potential for more extensive sediment oiling at Little Falls. Higher THC concentrations on sediments were predicted for CLB and mass balance results indicate that a larger portion of the total amount released was predicted to settle on the bottom after 24 hours, when compared to the Bakken scenarios. Maximum concentrations of 50 g/m^2 were predicted for Bakken, while some areas exceeded 500 g/m^2 for CLB.

For both oil types, the localized and patchy nature of sediment oiling is difficult to predict. Results are therefore helpful in indicating the potential presence of the amount of oil, rather than the exact location where it may be found, which is dynamic in time. Due to the lower viscosity of Bakken, the entrainment of oil, and ultimate oil-SPM interactions, lower level contamination (i.e., lower THC concentrations) of sediments was predicted to take place over a much larger area, when compared to the CLB. On the other hand, larger amounts of CLB were predicted to settle on the bottom, but over a much smaller areal extent, with localized patches. In all cases, it is important to note that less than 1% of the total amount of released oil (for both CLB and Bakken) was predicted to settle. In each case, the majority of the oil was predicted to oil shorelines and evaporate to the atmosphere.

Under low flow river conditions, with 100% ice coverage, the oil was predicted to rise within the first few miles downstream of the release location. The distance downstream that the oil was transported was mainly controlled by the river velocity and the density of the oils, which controlled its rise rate before reaching the ice at the surface. In general, CLB was predicted to oil slightly more areas of ice, while the Bakken was predicted to be more contained. A large portion of the soluble portion of both oils dissolved into the water column where it was transported downstream. Much larger portions of river were predicted to experience dissolved aromatic concentrations in excess of 5,000 ppb during low flow conditions with complete ice cover, when compared to average or low flow scenarios. Very limited shoreline and sediment oiling occurred in the winter scenarios, when compared to the ice free scenarios.

7.0 ASSESSMENT OF ENVIRONMENTAL EFFECTS OF OIL RELEASES

The assessment of environmental effects of crude oil releases begins with a description of the observed and expected effects of oil on key ecological and human receptors, including how oil behaves (i.e., its fate) in terrestrial, atmospheric and freshwater environments, and how it affects associated biological resources (Section 7.1). Information in this section is informed by a number of case studies with circumstances similar to those that might be encountered in the event of an oil release from a pipeline in Minnesota. This is followed (Section 7.2) by an assessment for each of the seven modeled sites in Minnesota that were determined to be representative of most of the predominant ecological units, major hydrological features, watercourse widths, and watercourse features along the preferred and alternative routes:

- Site 1—Mosquito Creek to Lower Rice Lake (Section 7.2)
- Site 2—Mississippi River at Ball Club (Section 7.3)
- Site 3—Sandy River (Section 7.4)
- Site 4—Shell River to Twin Lakes (Section 7.5)
- Site 5—Red River (Section 7.6)
- Site 6—Mississippi River at Palisade (Section 7.7)
- Site 7—Mississippi River at Little Falls (Section 7.8)

The location of these seven sites and the spatial extent of the assessment of environmental effects are illustrated on Figure 7-1.

The assessment of each site includes a description of the environmental setting at and downstream of the hypothetical release location, and a detailed discussion of the expected environmental effects of an oil release (based on two crude oil types that provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (CLB/CLWB)) on the physical, biological and human environments; namely:

- Terrestrial receptors (i.e., soil, groundwater, terrestrial, vegetation)
- Aquatic receptors (i.e., rivers, lakes, sediment, shorelines and riparian areas, wetlands, aquatic plants, benthic invertebrates, fish)
- Semi-aquatic wildlife receptors (i.e., amphibians and reptiles, birds, semi-aquatic mammals)
- Human and socio-economic receptors (i.e., air quality, human receptors, public use of natural resources)

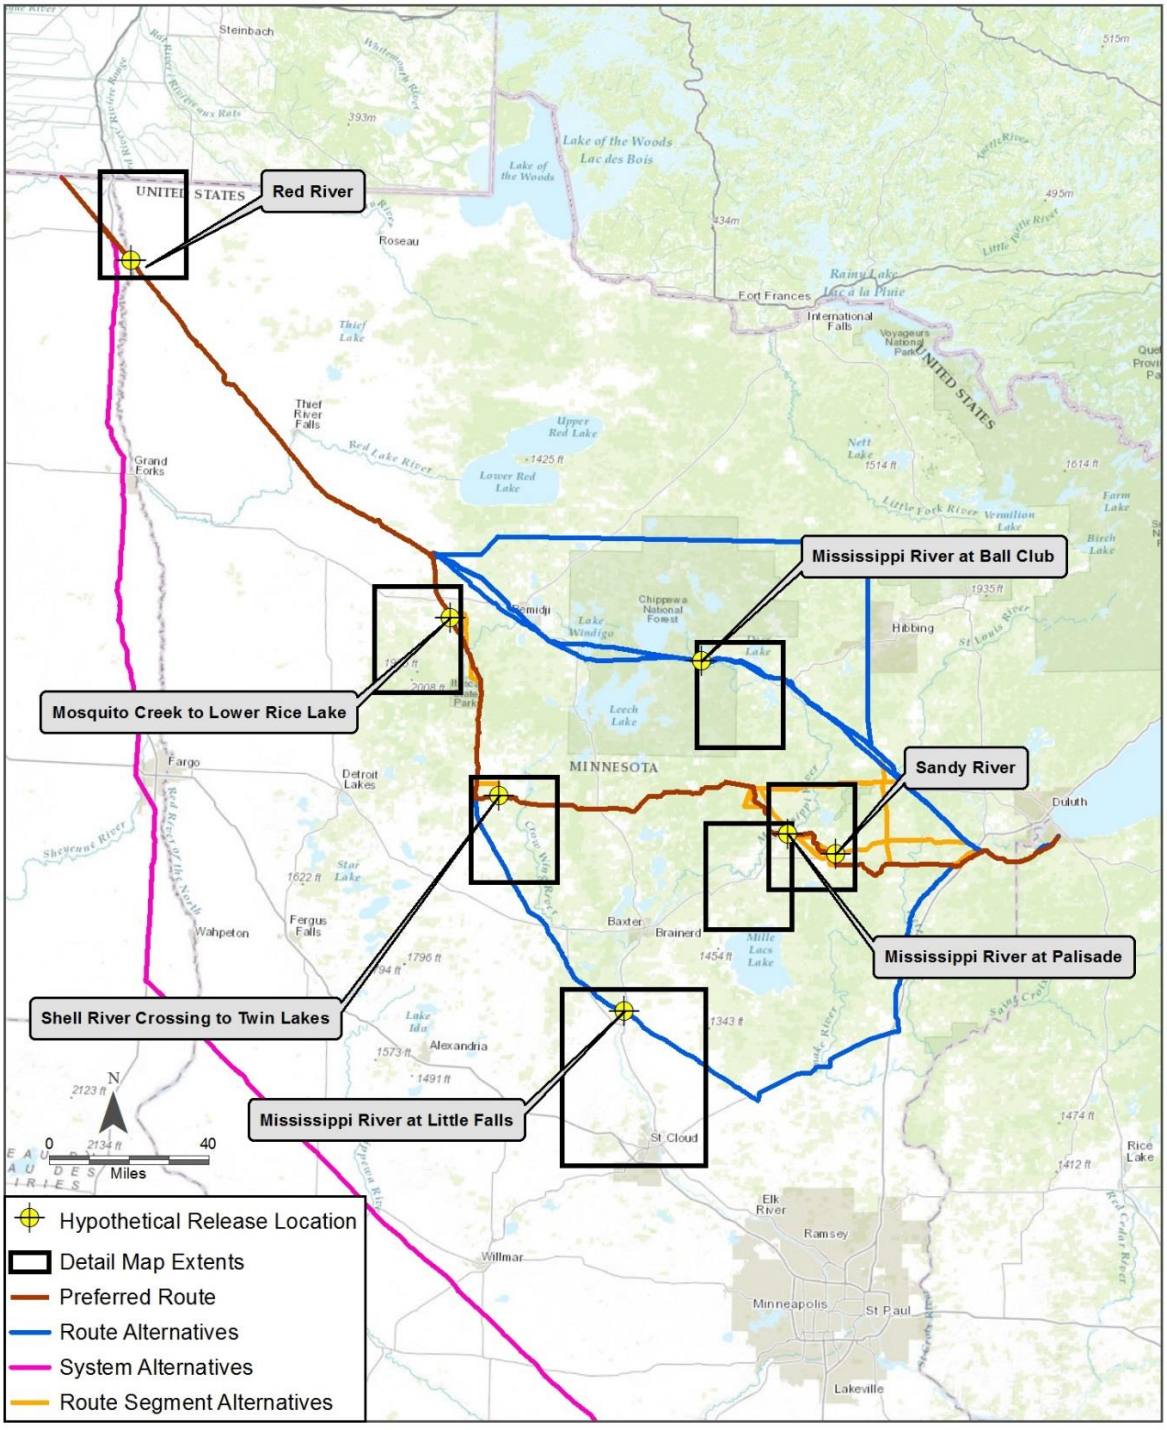

Figure 7-1 Locations of Hypothetical Release Sites and Spatial Extent of the Assessment of Environmental Effects

In addition, the potential overlap of oil releases with federally-designated (i.e., U.S. Department of Transportation [USDOT] PHMSA) HCAs and other sensitive locations not included in the USDOT PHMSA data (defined as AOIs) is included. HCAs include populated areas, unusually sensitive ecological areas, drinking water sources and commercially navigable waterways. Populated areas are broken down as high population areas (i.e., urban areas), and "other populated areas," which consist of smaller towns and villages. Ecologically-sensitive areas include imperiled species and ecological communities, threatened and endangered species, depleted marine mammals, and migratory water bird concentrations (USDOT PHMSA 2016a). The drinking water data consist of public water systems, source water protection areas, and sole source aquifers (USDOT PHMSA 2016b). Sources of these data for the environmental effects assessment are shown in Table 7-1.

Table 7-1 Sources of HCA Data

HCA Type	HCA Subtype	Source
Population Area	Other	USDOT PHMSA, 2011; 2016a; 2016b

		Provided by Enbridge in 2014

AOIs depict other sensitive locations where a release could have a detrimental impact. These areas include local Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks). Data for the AOI analysis were derived from multiple datasets provided on the Minnesota Geospatial Commons website (MN Geospatial Commons 2016), USGS Protected Areas Database of the United States (PAD-US; USGS 2015), and the Minnesota Department of Transpiration (MN DOT 2016; see

Table 7-2 Sources of AOI Data

An overall summary of the assessment of environmental effects of hypothetical crude oil releases at the seven representative locations is provided in Section 7.9.

7.1 REVIEW OF OBSERVED AND EXPECTED EFFECTS OF OIL RELEASES ON KEY ECOLOGICAL AND HUMAN RECEPTORS

7.1.1 Fate of Oils Released to Freshwater Environments

Crude oils and refined petroleum products are complex mixtures of hydrocarbon compounds derived from naturally occurring geological formations. When released into the environment, various weathering processes work to break down the hydrocarbons into primarily carbon dioxide and water. The rate of these weathering processes depends principally upon the type of oil (i.e., the specific mixture of hydrocarbon compounds present), the characteristics of the receiving environment (e.g., location of the release, season, and weather conditions), and the volume released, among other factors.

Individual crude oils and petroleum products are composed of differing mixtures of hydrocarbon compounds. Each has physical properties (e.g., viscosity, density, solubility) that reflect its chemical composition and affect its fate and transport once released into the environment (NRC 2003). For example, heavy oils (i.e., those with a higher percentage of heavy fractions, or high asphaltene and resin content) tend to be viscous and weather slowly because they do not readily spread into thin oil slicks, and they contain chemical constituents that resist degradation.

The high viscosity of heavy crude oil makes it difficult to pump and transport through a pipeline. Therefore, bitumen is often diluted with other petroleum products such as natural gas condensates. In addition to Bakken Crude, two of the products proposed for transport by the L3RP pipeline are CLB and CLWB. These two diluted bitumen (dilbit) petroleum products have been the subject of substantial review in the past several years.

Two recent high-profile studies of the behavior and fate of dilbits in the environment came to different key conclusions regarding their environmental fates.

The National Academies of Sciences, Engineering and Medicine (NAS 2015) formed a committee to study the relevant properties and characteristics of the transport, fate, and effects of diluted bitumen and commonly transported crude oils when released in the environment from U.S. transmission pipelines (NAS 2015). The committee concluded that:

> "In comparison to other commonly transported crude oils, many of the chemical and physical properties of diluted bitumen, especially those relevant to environmental impacts, are found to differ substantially from those of the other crude oils. The key differences are in the exceptionally high density, viscosity, and adhesion properties of the bitumen component of the diluted bitumen that dictate environmental behavior as the crude oil is subjected to weathering …" (NAS 2015).

The Royal Society of Canada likewise convened an expert panel to review the behavior and environmental effects of crude oil released into aqueous environments. The expert panel concluded that:

> "the dozens of crude oil types transported in Canada exist along a chemical continuum, from light oils to bitumen and heavy fuels, and the unique properties of each of these oil types (their chemical 'fingerprints') determine how readily released oil spreads, sinks, disperses, impacts aquatic organisms, including wildlife, and what proportion ultimately degrades in the environment. Despite the importance of oil type, the Panel concluded that the overall impact of an oil release, including the effectiveness of an oil release response, depends mainly on the environment and conditions (weather, waves, etc.) where the release takes place and the time lost before remedial operations." (Lee et al. 2015).

In this section the characteristics of light, medium, and heavy crude oils proposed for transport by the proposed L3RP pipeline are described. In addition, information is provided on how environmental factors such as season, water levels and physical processes may affect the behavior and fate of different crude oil/petroleum products if released into environments encountered by the proposed pipeline. A key objective of this section is to discuss information that will help reconcile the seemingly divergent conclusions of the two expert panels with regards to transport of dilbit products.

7.1.1.1 Oil Characteristics

CLB and CLWB crude oils are diluted bitumens with characteristic properties of density and viscosity falling in the upper range of values allowed by pipeline tariff specifications. General characteristics of CLB include an American Petroleum Institute gravity (API, a measure of how

heavy or light a petroleum liquid is compared to water) of 20.7°, a density of 0.93 at 15°C, and a sulfur content ranging between 3.6% and 4.7% (Environment Canada 2016). Similarly, CLWB has typical characteristics that include API gravity of 22.7° and density at 15°C of 0.92 (Horn 2016). Seasonal variation in environmental temperature affects the viscosity of diluted bitumen; therefore, the amount of condensate or other diluent added is adjusted through the year to meet shipping requirements. The bitumen feedstock used in CLB and CLWB remains consistent on a seasonal basis, but the CLWB contains relatively more diluent to maintain the desired viscosity characteristic during the winter months.

Bakken crude is a light sweet crude oil with an API gravity generally between 40° and 43° and a sulfur content less than 0.2 wt.%. A crude oil with less than 1 wt.% total sulfur content is referred to as being low-sulfur or sweet crude oil. A crude oil with more than 1 wt% total sulfur is referred to as being high-sulfur or sour crude oil. As such, Bakken crude oil is similar to many other light sweet crude oils produced and transported in the United States (Auers et al. 2014). The light end concentration of Bakken crude is between 3% and 9%, with 5% being the typical concentration (NDPC 2016). As a point of reference, the Energy Information Administration categorizes crude oil that has API gravity between 35° and 50° and less than 0.3 wt% sulfur as being light sweet. Bakken falls in the middle of those ranges for both properties (Auers et al. 2014).

BTEX compounds generally represent a small fraction in each of the oil products. Diluted bitumens appear to contain around 1% BTEX by weight (Zhou et al. 2015), varying principally in accordance with the properties and quantity of diluent added. Light crude oils tend to contain rather more BTEX (2 to 3% by weight, Zhou et al. 2015). Light crude oils and Bakken crude oil in particular would be expected to contain a larger fraction of both aliphatic and aromatic low boiling point hydrocarbons, and relatively less of the high boiling point and recalcitrant fractions such as resins and asphaltenes, than diluted bitumens.

The crude oil types discussed here (i.e., Bakken and diluted bitumen) represent products that exist on opposite ends of the spectrum of crude oil types commonly encountered in North America. This fact was recognized by Lee et al. (2015), but was obscured by the methodology employed by NAS (2015). The terms of reference established for the NAS committee led them to focus their evaluation of "commonly transported" crude oil types. As a result of this direction, the analysis carried out by NAS (2015) focused on the properties of Scotia Light (actually an ultralight crude or gas condensate produced in Nova Scotia, Canada, not likely to be transported by U.S. pipelines, and having API gravity 53.2°), and West Texas Intermediate (actually a light crude oil, API gravity 34.4 to 40.8), to the exclusion of the many medium and conventional heavy crude oils that allowed Lee et al. (2015) to identify diluted bitumens as belonging within a "continuum" of crude oil types.

The physical and chemical characteristics of released oils have a direct effect on their behavior and fate. Seasonal considerations and physical processes that affect the fate of released oils are also discussed in the sections below.

7.1.1.2 Seasonal Considerations for the Fate of Released Oil

The season in which a release occurs (and related freshwater levels during each season) can influence release behavior, fate, effects, and clean-up response actions. Seasonal variations in potential release behavior are addressed in this section.

Spring—Midsummer: For this analysis, the spring to midsummer is defined as the period when mid-continent streams and rivers exhibit seasonal high flow due to snow melt and drainage of temporarily stored groundwater. Water levels in ponds, lakes, and reservoirs are also seasonally high. Temperatures may range from cool to warm. The land is mostly snow-free, and biological productivity of land and water bodies is high.

Releases to land would directly affect soils and vegetation, although spreading of the released material is likely to be impeded by the vegetation. Releases to wetlands may float and spread if there is a free-water surface (as in a fen, marsh, or pond) or be absorbed if there is an abundance of vegetation or other organic matter (as in a bog). Currents, winds, and gravitational thinning forces would promote the spreading of releases that reach water bodies.

Weather, especially rapid warming periods and heavy rainfall, may cause rapid melting of snow on land and ice in rivers at this time of the year. These conditions can result in major flood flows that breach levees along larger rivers, erode river banks, and alter channels. If oil is released to a flooded area, oil could be distributed over a large area to adjacent terrestrial, wetland, and aquatic habitats that normally would not be exposed.

Late Summer—Fall: This period of the year extends from August until freeze-up of water bodies. Water levels in mid-continent streams, rivers, reservoirs, ponds, and lakes tend to be lower at this time of year than in the spring - midsummer period. Precipitation tends to be lower during the late summer and fall than in the spring - midsummer period, although strong storm events can still generate occasional flood flow periods. Oil released into water bodies will tend to remain within banks and strand along shorelines, limiting the potential for oiling of adjacent riparian, wetland, and terrestrial habitats.

Winter: Winter is the period when mid-continent water bodies are likely to be ice-covered and the land surface is likely to be frozen or covered with snow. Due to generally cold conditions, stream and river discharge may approach seasonally low levels, although periods of thaw may result in fluctuating flows. Oil released to the land generally would be slowed, although not necessarily stopped, by the snow cover. Releases reaching streams, rivers, and lakes could potentially be prevented from entering the water by snow and ice covering the water body. However, releases that penetrate ice might be more difficult to detect, contain, and clean-up.

Freeze-up and Breakup in Aquatic Environments: Freeze-up is the transitional time in the fall when streams, rivers, lakes and other water bodies begin to freeze. Breakup or spring melt is the transitional period when ice thins and breaks up, and river flows increase to freshet or flood

stage. Major floods may cause bank erosion and potentially pipeline failure, with the oil entering the river and likely being widely dispersed and difficult to contain or clean-up.

An oil release that results in oil reaching water bodies during either freeze-up or breakup may be difficult to contain, remove, and clean-up. The ice may not be strong enough to support people or equipment. In rivers, the oil may be transported several miles under the ice or in broken ice before it can be contained. Once the ice is strong enough to support people and equipment, it may be more difficult to detect the oil under the ice, and implement measures to affect rapid containment/clean-up at or near the release site.

7.1.1.3 Physical Factors Affecting the Behavior and Fate of Released Oil

The primary and shorter-term processes that affect the fate of released oil are spreading, evaporation, dispersion, dissolution, and emulsification (Payne et al. 1987; Boehm 1987; Boehm et al. 1987; Overstreet and Galt 1995). These processes contribute to the overall process of oil weathering (the physical and chemical change of released oil). Weathering dominates during the first few days to weeks of a release. A number of longer-term processes also occur, including photo-degradation, biodegradation, auto-oxidation, and sedimentation. These longer-term processes are more important in the later stages of weathering and usually determine the ultimate fate of the released oil not recovered by the clean-up program.

The chemical and physical composition of oil changes with weathering. Because of evaporation and dissolution, the effects of weathering are generally rapid (one to a few days) for hydrocarbons with lower molecular weights (e.g., gasoline, aviation gas, and diesel). Degradation of the higher weight fractions (e.g., medium and higher molecular weight components of crude oil, and bitumens in CLB and CLWB) is slower and occurs primarily through microbial degradation and chemical oxidation.

The weathering or fate of released oil depends on the oil properties and on environmental conditions, both of which can change over time.

Spreading: Spreading, either by gravity (e.g., unconfined oil on the ocean or a large lake) or by advection (e.g., oil being carried away from a release location by river flow), reduces the bulk quantity of oil present in the vicinity of the release, but increases the spatial area over which adverse effects could occur. Thus, oil in flowing systems (e.g., rivers and creeks) rather than confined systems (e.g., wetlands, ponds, and lakes) would be less concentrated in any given location, but could cause environmental effects, albeit reduced in intensity, over a larger area.

Spreading and thinning of released oil also increases the surface area of the slick, enhancing surface-dependent fate processes such as evaporation, biodegradation, photo-degradation (see below), and dissolution. Previous inland oil releases indicate, though, that the degree of spreading of oil from the release source may be constrained by natural conditions in the vicinity of the release site. For example, released oil will tend to adhere to riparian bank, lake shores,

and wetlands with which oil contact is made. On land, oil spreading is limited; but it may occur immediately once the oil reaches a water surface, and will continue to spread out into a thin film unless constrained through interactions with riparian banks, wetlands, shorelines, man-made structure, or response actions. Small amounts of crude oil can spread on water into a very thin layer ("sheen"). Sheening represents an impairment of water quality that can determine the degree of oil recovery that is required (NAS 2015).

Light crude oils such as Bakken crude are anticipated to spread more quickly due to their low viscosity relative to heavier oils such as CLB and CLWB. The spreading of oil on water may be one of the most important processes during the first hours of a release, provided the oil pour point (the temperature at which it becomes a semi-solid and loses its flow characteristics) is lower than the ambient temperature (Lee et al. 2015).

Oil Particle Aggregate Dynamics: The fate of released oil may be significantly affected by the presence of mineral or organic particulate matter in terrestrial and aquatic environments. The manner in which oil interacts with particles and its eventual transport and fate depend on the physical properties of the oil and the particles, as well as environmental conditions, including the geomorphic setting, weather, currents, and vertical mixing of the water column (Lee et al. 2011; Lee 2002).

Crude oil contacting soil will adsorb or adhere to soil particles—usually binding most strongly to particles in organic soils and less strongly to particles in sandy soils. In aquatic environments, such as rivers, floodplains, wetlands, lakes, and associated shorelines, suspended particles affect the fate and transport of released oil (Muschenheim and Lee 2002; Owens and Lee 2003; Khelifa et al. 2005a, 2005b, and 2005c; Sun and Zheng 2009; Gong et al. 2014).

Combinations of oil and particles have various names, including clay-oil flocculation (Bragg and Yang 1995), oil-mineral aggregates, and oil-suspended sediment-aggregates (Khelifa et al. 2002) depending on the type of particle involved in the interaction. The term oil particle aggregate (OPA) is a generic term that includes a wide range of particles containing both mineral sediment and organic matter in association with oil that may be retained in suspension and (or) settled out (Fitzpatrick et al. 2015). Formation of OPAs happens naturally when oil and suspended particles mix in turbulent water (Lee 2002; Muschenheim and Lee 2002; Owens and Lee 2003; Khelifa et al. 2005a; Sun and Zheng 2009; Gong et al. 2014). Major factors affecting the formation of OPA are (1) the quantity, viscosity and chemical composition of the oil; (2) the quantity, type, and surface properties of the particles; (3) the magnitude and variability in physical energy of the aquatic environment; (4) the temperature; (5) oil-water interfacial tension; and (6) (while not applicable in northern Minnesota) the salinity of the water (Lee 2002; Khelifa et al. 2002; Payne et al. 2003).

The first step to forming OPAs in the water lies with the initial breakup of a slick of oil into oil droplets. Once released into a water body with turbulence created by waves or currents, floating oil can break up into droplets and reach a stable droplet size distribution (DSD) relatively

quickly, perhaps in minutes to tens of minutes (Zhao et al. 2014a). Smaller droplets are generated when the oil-water interfacial tension is small and/or the oil viscosity is small. However, oil viscosity can increase by orders of magnitude among different types and temperatures of oils. Oil viscosity substantially increases as the temperature lowers to near oil's pour point. Further, the viscosity of a heavy crude oil or dilbit product such as CLB or CLWB is higher than that of light crude such as BAK oil (Fitzpatrick et al. 2015).

Evaporation: Evaporation is the primary mechanism for loss of low-molecular-weight constituents and light oil products. As lighter components evaporate, remaining petroleum hydrocarbons become denser and more viscous. Oil evaporation can be considerably slowed down by the formation of a "crust" or "skin" on top of the oil. This happens primarily on land where the oil layer is not agitated by water movement (Fingas 2015a). The rate of evaporation is very rapid immediately after oil release and then slows considerably (Fingas 2012). About 80% of evaporation occurs in the first few days after a release (Fingas 2015a).

Oil undergoing evaporation loses its more volatile and readily degraded components, leaving behind those components that weather more slowly. Hydrocarbons that volatilize into the atmosphere are broken down by sunlight into smaller compounds. This process, referred to as "photo-degradation," occurs rapidly in air; the rate of photo-degradation decreases as molecular weight increases.

While evaporation tends to reduce acute toxicity and result in overall mass reduction, the residual components may exhibit chronic, sublethal toxicity properties. Examples of sublethal effects observed in aquatic biota include external and internal lesions, developmental abnormalities in early-life stages, and behavioral changes in feeding and breeding. Delayed effects are also a possibility with measurable effects arising later in life or in subsequent generations (Dupuis and Ucan-Marin 2015).

Much of the light components of Bakken crude and the condensate diluent of CLB and CLWB will volatilize within the first few days of an oil release. Losses through volatilization likely are more pronounced in Bakken crude relative to CLB and CLWB.

Dispersion: Dispersion refers to the entrainment of oil droplets in the water column. The extent of oil dispersion depends on the interfacial tension between oil and water, oil viscosity, and the mixing energy that may be driven by wind and currents (Zhao et al. 2014b). The interfacial tension between the oil and water does not vary widely among oil types. The range is typically less than twofold. The mixing energy varies across environments, and over space and time in a particular environment (e.g., rivers passing over dams, and windy versus calm weather on lakes) (NAS 2015).

The DSD of oil dispersed in water plays an important role in the behavior of oil in the aquatic environment. Larger droplets are more buoyant than smaller droplets and thus rise more readily to the water surface, regardless of whether they were released underwater, or on the water

surface and entrained into the water column by turbulence. The DSD affects not only the transport but the fate and toxicity of released oil. Increasing the proportion of small droplets increases the surface area per unit mass of oil, increasing the dissolution of hydrocarbons in the water column (Reddy et al. 2012) and their potential for bioaccumulation via transport across biological membranes (NAS 2015).

It is anticipated that Bakken crude will disperse more readily than CLB or CLWB products, if released into a water body.

Dissolution: Dissolution involves the more water-soluble components of a crude oil dissolving in the water column. Dissolution is not the primary process controlling the fate of oil in the environment. More commonly, oil floats, strands on shorelines/riparian banks, or volatilizes. The range of oils (i.e., Bakken crude through to CLB and CLWB) that would be transported by the proposed pipeline is lighter than water.

Some crude oil components are water-soluble and, to the extent that dissolution does occur, it is one of the primary processes affecting the toxic effects of a release to aquatic organisms, especially in confined water bodies. The potential for dissolution decreases with increasing hydrocarbon molecular weight and decreasing water temperature. Aromatic compounds are generally more water-soluble than aliphatic compounds having the same number of carbon atoms. The BTEX compounds are among the more water soluble hydrocarbon compounds and are of particular relevance to short-term or acute toxicity to aquatic life.

Emulsification: Emulsification is the incorporation of water in oil as a colloidal suspension. During emulsification, small drops of water become surrounded by oil. External energy from wave or strong current action is needed to naturally emulsify oil. In general, heavier oils emulsify more readily than lighter oils, although recent reports suggest that diluted bitumens do not readily emulsify. The oil could remain in a slick, which could contain as much as 70% water by weight, and could have a viscosity of a hundred to a thousand times greater than the original oil. Water-in-oil emulsions often are referred to as "mousse." Emulsification is more common in large water bodies (e.g., large lakes, major rivers, and the ocean) where waves and/or currents mix the surface waters, than in smaller water bodies where this mixing energy is usually much less. The high viscosity results in a semi-solid or gel, which contributes to the persistence of the emulsified oil and makes clean-up more difficult.

Benthic Deposition/Sinking: A recent National Academies of Science, Engineering and Medicine report (NAS 2015) states that diluted bitumen products such as CLB and CLWB (dilbits), if released to a waterbody, can sink and accumulate on the underlying bed leading to difficult cleanup. Specifically, NAS (2015) states that immediately after a release, exposure to the environment begins to change released diluted bitumen through various weathering processes. The net effect is a reversion toward properties of the initial bitumen. An important factor is the amount of time necessary for the oil to weather into an adhesive, dense, viscous material. For any crude oil release, lighter, volatile compounds begin to evaporate promptly. In the case of

diluted bitumen, a dense, viscous material with a strong tendency to adhere to surfaces begins to form as a residue, creating particular challenges in those cases where the residue reaches water bodies and submerges or sinks to the bottom of a water body. The density of the residual oil does not need to reach or exceed the density of the surrounding water for this to occur, since the crude oil may combine with particles present in the water column to submerge, and then remain in suspension or sink (NAS 2015).

In essence, NAS (2015) posits that the diluent in dilbits will immediately undergo weathering leaving leftover bitumen to sink due to its inherent high density or accommodation of suspended sediments/particulates.

In comparison, a recent Royal Society of Canada study (Lee et al. 2015) indicates that a driving factor in whether or not dilbits sink is the amount of loss of the diluent following release of the product to a water body. Specifically, the density of many crude oils, including diluted bitumen products, is less than that of both fresh water (~1 g/cm^3) and sea water (~1.03 g/cm^3). Therefore, these oils will float when released onto or into water. However, bitumen by definition has a density greater than 1 g/cm^3 and, if diluent evaporates from dilbit during a release, the residual bitumen will become more dense and may become submerged or sink. Even so, oil droplets of density ~1.0 can be neutrally buoyant and remain suspended in the water column, especially if present in turbulent water such as in a rapidly flowing river or high wave energy system (Lee et al. 2015).

While the amount of diluent lost to weathering following release is critical to whether or not dilbits sink, the degree of evaporation and dissolution of diluent is poorly understood. The Royal Society of Canada report (Lee et al. 2015) further indicates that there is debate about whether 100% of the diluent component of bitumen blends can be lost by natural evaporation (Fingas 2015b) or whether the residual bitumen/heavy oil will retain some of the diluent components as intimately blended constituents, conferring novel properties on the partially weathered oil (Winter and Haddad 2014). This is particularly important for predicting if weathered dilbit will float or sink in water. The observation of evaporative mass losses of less than 20% after rigorous weathering at environmentally-relevant temperatures for dilbits nominally containing greater than or equal to 30% diluent, suggests that a substantial proportion of diluent remains intimately associated with bitumen (Lee et al. 2015).

Photo-Degradation: Photochemical processes result from exposure of released oil to sunlight, leading to cleavage and formation of covalent bonds. Oxygen is typically incorporated into the products and thus the term photo-oxidation is commonly used (NAS 2015). These oxidized products include both carbon dioxide and other oxygenated compounds (Aeppli et al. 2012). Typically, aromatic hydrocarbons are transformed more rapidly than alkanes (Garrett et al. 1998), thereby increasing the relative abundance of resins and asphaltenes in the residual oil (Aeppli et al. 2012; Prince et al. 2003). In one set of laboratory experiments, the photo-oxidation of crude oil in fresh water under direct ultraviolet irradiation showed oxidation of 5% of the

branched alkanes, 9% of the linear alkanes, and 37% of the aromatic hydrocarbons (D'auria et al. 2009; NAS 2015).

Photo-degradation of oil increases with greater solar intensity. It can be a significant factor controlling the disappearance of a slick, especially of lighter constituents, but it would be less important during cloudy days and in winter months.

Due to the relative increase in spreading and relatively higher fractions of lighter aromatic petroleum components relative to asphaltene components, Bakken crude is likely subject to increased photo-oxidation relative to CLB and CLWB.

Biodegradation: Biodegradation is the breakdown of compounds by native or introduced microorganisms. Biodegradation of oil by native microorganisms, in the hours to days following an oil release, would likely not be a significant process controlling the fate of oil in water bodies previously unexposed to oil. Although oil-degrading microbial populations are ubiquitous at low densities, a sufficiently large population must become established before biodegradation can proceed at any appreciable rate. Biodegradation is typically a long-term (weeks to years) process that reduces both the toxicity and volume of released oil.

Biodegradation can occur either aerobically or anaerobically, with aerobic processes typically occurring more rapidly and extensively. Biodegradation is accelerated in the presence of abundant oxygen and nutrients (Boufadel et al. 2010) at moderate temperature, salinity (where applicable), and reasonable oil-water interfacial surface area (Geng et al. 2014). At this time, there are no quantitative field studies on the biodegradation of releases of diluted bitumen such as CLB and CLWB, but saturates and aromatics are expected to biodegrade within weeks to years (NAS 2015).

7.1.1.4 Summary of Factors Influencing the Fate and Behavior of Released Oils

The environmental fate of released oil and oil products is controlled by many factors. Major factors affecting environmental fate include the release volume, release rate, oil temperature, terrain, receiving environment, time of year, and weather. For example, Bakken crude oil, a light, sweet crude oil, would weather differently than dilbit oils such as CLB and CLWB, in that the light ends of Bakken and the condensate diluent of CLB and CLWB would evaporate faster and dissolve to a greater degree in water than the heavier ends of Bakken and the bitumen component of CLB and CLWB.

The characteristics of the receiving environment, such as the type of land cover, soil porosity, land surface topography and gradient, type of freshwater body, particulate load in the water, presence of ice and/or snow cover on water or land, and flowing water current velocity, would affect how the release behaves. In ice-covered waters, many of the same weathering processes occur as in open water. However, ice changes the rates and relative importance of these processes (Payne et al. 1991).

The time of year when a release occurs has a major effect on the fate of crude oil. The time of year controls climatic factors such as the temperature of the air, water, or soil; depth of snow cover; presence of ice; and the depth of the active (soil frost) layer. During winter, colder air temperatures can modify the viscosity of oil so that it would spread less and potentially solidify. Temperature also affects the rate of evaporation of the volatile fraction of hydrocarbons. Frozen ground would limit the depth of penetration of any release. Weather could also affect the ability to detect, contain, or clean-up a release.

The physical and chemical processes discussed herein, which govern the fate of released oils, will drive exposure and manifest effects to ecological, land cover, and human receptors. For example, lighter oils such as Bakken tend to more readily evaporate and dissolve relative to dilbits, resulting in potential effects to biological communities residing in the water surface, column, and atmosphere, as well as result in potential inhalation exposure for human receptors. Comparatively, heavier oils such as dilbits tend to adhere to encountered riparian banks and lakeshores, resulting in marked exposure to biological communities residing there. Importantly, the specifics of any given incident will drive the fate and effects of released crude and refined petroleum products.

7.1.2 Land Cover Receptors

7.1.2.1 Air/Atmosphere

Section 109(b) of the Clean Air Act (CAA) requires that the USEPA establish National Ambient Air Quality Standards (NAAQS) "requisite to protect" public health and public welfare (40 CFR Part 50). The CAA identifies two class types of NAAQS: primary standards and secondary standards. Primary standards are limits set to protect the public health of the most sensitive populations, such as asthmatics, children and the elderly. Secondary standards are limits set to protect public welfare such as protection against visibility impairment or damage to vegetation, wildlife and structures. The CAA requires the USEPA to periodically review and, if new data indicate, update the NAAQS.

The USEPA has promulgated NAAQS for six criteria pollutants: ozone, particulate matter (PM), sulfur dioxide (SO_2), nitrogen dioxide (NO_2), carbon monoxide (CO), and lead. Particulate matter (PM) is a term for particles in the air, such as dust, soot, smoke, and liquid droplets. Standards for PM are categorized on the size of the PM based on the aerodynamic diameter of the particle. The term PM_{10} represents particulate matter with an aerodynamic diameter less than 10 µm and $PM_{2.5}$ is PM with a diameter less than 2.5 µm.

In Minnesota, the MN PCA monitors and regulates air pollution. MN PCA is required to develop regulations, referred to as the State Implementation Plan (SIP) to outline how the areas under their jurisdiction will attain and maintain ambient air concentration levels in compliance with the NAAQS. Within their SIP, MN PCA has developed state air quality regulations under Section 7009.0800 of the Minnesota Administrative Rules. In general, the state standards mirror the USEPA

NAAQS. The primary difference is that the state has also developed ambient air quality standards for hydrogen sulfide (H_2S). In a proposed amendment to the state air quality rules published on February 29, 2016, the state has stated its intention to align their criteria pollutant standards with the current USEPA NAAQS, while retaining the H_2S standard. Long term ambient air monitoring has demonstrated that Minnesota attains compliance with all USEPA NAAQS within the counties traversed by this Project and throughout the state with the exception of a localized area in the Minneapolis-St. Paul area that is classified as nonattainment for the lead NAAQS.

The MN PCA has also worked with the Minnesota Department of Health (MN DH) to assess the health risk from air pollution beyond the NAAQS. While attainment of the NAAQS is a good overall indicator of air quality, the NAAQS do not address potential issues associated with individual chemicals or chemical species. The MN DH and MN PCA have identified a list of chemicals referred to as air toxics that cause or may cause cancer or other serious health effects or adverse environmental and ecological effects. Health Risk Values, Health-Based Values, and Risk Assessment Advice have been established as benchmarks to aid the agencies in air permitting and environmental review decisions and to prioritize air toxic emission reduction programs across the state. Chemicals for which ambient air values have been developed include BTEX and naphthalene. These are chemicals commonly found in crude oil. The standards that have been developed by MN DH represent acute (one-hour average), subchronic (13-week average), and chronic (annual average) exposures. The chronic standards define levels of increased risk to human health over the long term, or lifetime, of exposures to a specific chemical, whereas an acute standard addresses the short-term risks associated with a transient event such as an oil spill.

Crude oil is a complex mixture of organic compounds. The organic compounds, also referred to as hydrocarbons, are molecules primarily made up of carbon and hydrogen atoms. These molecules may also contain small amounts of elemental sulfur, nitrogen, and oxygen. Some metals and other trace compounds such as hydrogen sulfide also may be found in the mixture.

The number and arrangement of the carbon atoms in each compound define the physical properties of the compounds such as whether they are normally found as gases, liquids or solids and the density of the compound. Compounds with less than five carbon atoms such as methane (one carbon) and ethane (two carbons) are generally found in their gaseous form at standard conditions (also referred to as normal conditions) of temperature and pressure (e.g., conditions found near ground level in the atmosphere). Slightly larger compounds with about 5 to 10 carbon atoms (e.g., octane, which has 8 carbons) found in gasoline are liquids at standard conditions. In this range, the shorter chained compounds will readily evaporate (or volatilize) if exposed to air and are; therefore, referred to as volatile organic compounds (VOCs). Other compounds in this range are the BTEX compounds, which are generally considered toxic chemicals with Health-Based rules established by MN DH.

Organic compounds with about 11 to 20 carbon atoms can be very complex. Within this range, there is a group of compounds (including naphthalene) that are liquid or solid at standard conditions, but which will evaporate or sublimate over time. These compounds are referred to as semi-volatile organic compounds and include fuel oil and a family of chemicals referred to as PAHs. The largest hydrocarbon compounds, having 20 carbon atoms or more, can be found in products such as lube oils or asphalt. These are generally thick, viscous liquids or waxy solids under standard conditions.

Crude oil is a complex mixture of all of these classes of hydrocarbons. Depending on the geographic area or geological formation from which crude oil is recovered, the relative composition of volatile and non-volatile compounds may vary considerably. Industry classifies crude oil into three general categories (light, medium and heavy) based on a measure of density (API gravity) which reflects the chemical composition of the oil. In transitioning from light to heavy oils, the percentage of volatile organic compounds typically decreases, and the fraction of non-volatile compounds increases. Bitumen is a very heavy type of crude oil that contains very little volatile hydrocarbon. However, depending upon the type of diluent used to manufacture diluted bitumen (dilbit), the volatile content of diluted bitumen may be relatively high (i.e., similar to that of a light oil) or very low.

The physical characteristic used by the petroleum industry to classify crude oil is the specific gravity or density of the mixture. For crude oils, the density of the material is reported as a dimensionless number referred to as API gravity. API gravity has an inverse relationship with density, therefore the less dense the oil, the higher the API gravity is of the mixture. A light crude oil is a material with an API gravity greater than 31.1° (Speight 2014; Lee et al. 2015). Medium crude oils have an API gravity between 31.1° and 22.3° (Speight 2014; Lee et al. 2015). Heavy crude oils have an API gravity less than 22.3° (Speight 2014; Lee et al. 2015). For comparison, a chemical with a density equal to that of water would have an API gravity of 10°.

A crude oil with a high API gravity will generally have a high concentration of VOCs and low viscosity. Viscosity is the property that defines how easily a liquid will flow and spread out. A low viscosity liquid, such as gasoline, has low internal friction and will easily spread out into a thin film as a result of gravity. A highly viscous material like asphalt or bitumen will not readily spread. The viscosity of a material changes with temperature, with an increase in temperature resulting in a decrease in the viscosity of the material.

The high viscosity of bitumen makes it difficult to pump and transport through a pipeline. Therefore, bitumen is either heated or diluted with another petroleum product such as natural gas liquids (condensate) or synthetic oil in order to lower its viscosity. Bitumen may be diluted by 10 to 40% with a diluent in order to meet standards for pipeline transportation.

In addition to being described as a function of density and viscosity, crude oils can also be classified as being either “sweet” or “sour”. A crude oil with less than 1 wt% sulfur content is referred to as being low-sulfur or sweet crude oil. A crude oil with more than 1 wt% sulfur is

referred to as being high-sulfur or sour crude oil. Typically crude oils range from less than 0.1–5 wt% sulfur. The sulfur content is important relative to the potential perceived odor from the material and the possible emission of H_2S, a toxic gas, from an oil release.

Of the six USEPA criteria air pollutants, the pollutant most theoretically likely to be affected by a crude oil release (although not contained in the crude oil) would be ozone. Ground-level ozone is produced on hot, sunny days by a chemical reaction between VOCs and oxides of nitrogen (NOx). Volatile organic carbon compounds are released by many activities, including the use of paints and solvents. NOx emissions are released from motor vehicles, power plants, and other activities that require fuel combustion. Levels of ozone are dependent on the amount of VOCs and NOx in the air, as well as weather conditions including sunlight, temperature, and wind speed and direction. Based on the need for specific meteorological conditions and the time delay for ozone to form in the atmosphere, the more immediate concern of the local community would be the short term exposure to VOCs (including benzene), H_2S or other specific chemicals, in addition to any odors associated with the volatilization of the crude oil following a release. To better define how oil releases have affected the local air quality, a review of historical data and laboratory studies was performed.

7.1.2.1.1 Observed Effects

The following section summarizes a review of some historic oil releases and their environmental effects on local air quality (only) following the release. This section also reviews some laboratory studies that have been completed to better define environmental effects on air quality from oil releases.

> ***Exxon Valdez Release, Alaska**: A study performed by Hanna and Drivas (1993) evaluated the VOC emissions from the Exxon Valdez Oil Release. The purpose of the study was to "reconstruct the time and space variation of air concentrations from the Exxon Valdez oil spill on March 24, 1989 in Prince William Sound, Alaska." The author stated that as much as 25% of the oil may have evaporated during the first two weeks following the release and all of the VOC or BTEX compounds evaporated within a few hours. The study concluded:*
>
> 1. *Benzene, toluene, and n-hexane evaporated completely within about 12 hours of the spill, and the evaporation was primarily diffusion-limited.*
> 2. *The less volatile compounds (e.g., n-pentadecane) evaporated at a much slower, more constant rate over the first two weeks, and their evaporation was controlled primarily by mass-transfer to the air.*

The first conclusion indicates that the evaporation rate of the more volatile components was limited by the ability of the volatile compounds to travel within the layer of oil floating on the water and come into contact with the air, where they evaporated immediately. The second conclusion indicates that the evaporation of the less volatile components of the oil was limited by temperature, airflow, and the physical properties of the compounds, such as vapor pressure.

The mass-transfer process would require more time to complete than the diffusion-limited process.

Environment Canada: *Experimentation was conducted by the Emergencies Science Division of Environment Canada on crude oil evaporation (Fingas 1999). The purpose of the study was to understand the evaporation process during an oil release and to develop an oil release behavior model. Through a series of studies the author determined that up to 75% by volume of light crude oils were lost to evaporation in the first few days following a release. The value reported was 40% for a medium crude oil and 5% for a heavy crude oil. In this study, the author concluded that:*

1. *Evaporation rate of several oils with increasing wind speed shows that, unlike water, the evaporation rate does not change significantly except for the initial step over 0-level wind*
2. *Increasing area does not significantly change oil evaporation rate*
3. *Decreasing thickness does not increase oil evaporation rate*
4. *Volume or mass of oil evaporating correlates with the evaporation rate*
5. *Evaporation of pure hydrocarbons with and without wind (turbulence) shows that compounds larger than nonane and decane are not boundary-layer regulated*

The author also stated, "The fact that oil evaporation is not strictly boundary-layer regulated implies a simplistic evaporation equation will suffice to describe the process. A simple equation of the form, evaporation = constant x logarithm of time, is sufficient to describe evaporation. The following processes do not require consideration: wind velocity, turbulence level, area, thickness, and scale size. The factors found to be important to evaporation are time and temperature." Therefore, Fingas's conclusion mirrors the finding of Hanna and Drivas, that evaporation of the larger compounds in the crude oil matrix is constant based on the temperature and controlled by mass-transfer processes.

OSSA II Pipeline, Bolivia: *On January 30, 2000, a fracture developed on the OSSA II pipeline over the Rio Desaguardo in Bolivia releasing 29,000 barrels of mixed crude oil and condensate into the river during a high flow event. At the time of the release, the pipeline was carrying a heavy crude oil diluted with kerosene-range petroleum product. Studies (Henshaw et al. 2001; Douglas et al. 2002) evaluated the weathering of the crude oil over the months following the spill. Samples of raw crude oil were compared to samples of stranded oil collected along the river banks following the release.*

Douglas concluded that the light hydrocarbons (3 to 18 carbons), which includes the BTEX compounds, were almost completely removed by evaporation. The

results indicated that as much as 45% of the released oil may have evaporated. However, there are no reported data on air quality for this event.

Wabamun Lake Train Derailment, Alberta, Canada: *On August 3, 2005, a CN freight train derailed near the Village of Whitewood Sands in Alberta, Canada. Approximately 4,500 barrels of Bunker C fuel oil were released. The Bunker C fuel oil was being delivered to be utilized as asphalt stock. The Bunker C contained no BTEX and was primarily composed of non-volatile, long-chained organic compounds. A sample of the Bunker C fuel oil was collected three days after the derailment from a pool near the ruptured rail cars. A fingerprint analysis of the pooled oil indicated that the oil was identical to samples of the Bunker C fuel oil produced by the refinery from which the material originated (Hollebone et al. 2011). The lack of physical change to the oil over the three days indicates that there was minimal loss of oil constituents to evaporation.*

Trans Mountain Pipeline, Burnaby, British Columbia: *In July 2007, a backhoe accidentally struck the Trans Mountain Pipeline in Burnaby, British Columbia. A total of 1,500 barrels of Albian Heavy Synthetic crude oil blend, a type of partially upgraded heavy crude oil known as a dilsynbit, was sprayed into the air and covered surrounding streets and buildings (Trans Mountain Pipeline ULC 2014). Air quality monitoring began immediately following the incident. VOC levels declined rapidly during the clean-up efforts (Eykelbosh 2014). The residents that were evacuated in response to the spill reported various symptoms including headache, nausea, dizziness, upper respiratory tract irritation and eye irritation. No long term effects study has been completed.*

Immediately following the spill, approximately 225 people were evacuated by the fire department. More than half of the people were able to return to their homes that evening. A total of 101 people representing 42 families spent the night of the release in other accommodations away from their homes (Trans Mountain 2015).

Marshall, Michigan: *On July 26, 2010, Enbridge reported a 30-inch pipeline had ruptured near Marshall, Michigan. The break resulted in the release of an estimated 20,000 barrels of a crude oil mixture of which approximately 8,200 barrels reached Talmadge Creek and the Kalamazoo River (Enbridge 2013a). The pipeline was transporting Western Canadian Select and CLB crude oils. These crude oils are classified as heavy crude oils (diluted bitumens). To allow the heavy crude oil to flow through the pipeline a diluent was added to the crude oil at a concentration of about 30%.*

A review of the USEPA certified air quality ozone monitoring data collected by Michigan Department of Environmental Quality (MI DEQ) (USEPA 2016) for

southern Michigan on the day of the release and through the remainder of 2010 indicates that there were no violations of the ozone NAAQS.

Beginning on July 26, 2010 and continuing through 2012, the USEPA and Enbridge through their contractors routinely monitored the air quality throughout the project area. Initial testing was performed for VOCs, H_2S, CO, and benzene. Numerous methodologies were employed to monitor for emissions. Human health screening levels were developed and decision trees were created by the Agency for Toxic Substances and Disease Registry (ATSDR), the Calhoun County Public Health Department, and Michigan Department of Community Health (MI DCH) to determine if evacuation orders would be required (MI DCH 2014a). An initial screening level was developed by MI DCH for acute (short-term) exposure to benzene and was set at a level of greater than 200 parts per billion (ppb)at which evacuation would be recommended, if confirmed by a second test (MI DCH 2014a). Longer term, chronic screening levels were developed by MI DCH to determine when homes could be re-occupied and were set at a level of 6 ppb benzene. The 6 ppb level cited by MI DCH is a level derived by the ATSDR as an intermediate-duration inhalation Minimal Risk Level for inhalation exposures to benzene.

For comparison, in the state of Minnesota, the MN DH and MN PCA health based guidance for benzene sets an acute (short-term) exposure level of 1,000 micrograms per cubic meter, which is roughly equivalent to 320 ppb (MN DH 2016). The MN DH guidance sets a benchmark of 1.3 to 4.5 micrograms per cubic meter for longer term (chronic) exposures, which is equivalent to a range of 0.4 to 1.5 ppb (MN DH 2016)).

MI DCH prepared a report (MI DCH 2014a) assessing the extent of air contamination as monitored throughout the project period. MI DCH divided the data for 2010 into three time frame groupings:

- *Initial Response Period from July 26 through July 28, 2010*
- *Voluntary Evacuation Period from July 29 to August 17, 2010*
- *Post Evacuation Period from August 18 to December 31, 2010*

The data were primarily collected in four locations, which are identified as: 1) the Voluntary Evacuation Area (along Talmadge Creek from the release site to the confluence with the Kalamazoo River, 2) Squaw Creek Subdivision (west of the confluence of Tallmadge Creek and the Kalamazoo River about 2.5 miles downstream from the release), 3) the town of Ceresco (about 6 miles downstream from the release), and 4) Baker Estates Subdivision in Battle Creek (about 13.5 miles downstream from the release). Additional samples were also collected in the area referred to as the Oil Release Site, but no homes were located in this area.

Initial Response Period (July 26 through July 28, 2010)

During the Initial Response Period (the first three days following the release), air sampling was begun the day of the release using hand-held meters and Draeger tubes. More extensive monitoring began on the day following the release when more sophisticated monitoring was performed, which included the use of mobile field gas chromatograph monitors and the collection of Summa canister and Tedlar bag samples, which were sent to a laboratory of chemical analysis.

For VOCs, a screening level of 1,000 ppb of total VOCs was utilized by MI DCH to indicate if further chemical specific monitoring (such as benzene) might be appropriate. About half of the measured concentrations exceeded 1,000 ppb in the evacuation area, Squaw Creek Subdivision, and in Ceresco. However, VOCs were not detected in air at Baker Estates. (MI DCH 2014a). The results of the VOC monitoring during the Initial Response Period are shown in Table 7-3.

Table 7-3 Total VOC Concentrations in ppb during the Initial Response Period

A screening level of 60 ppb benzene was utilized by MI DCH to indicate if use of the mobile field gas chromatograph monitor was appropriate. The screening samples were collected primarily using an UltraRAE real-time monitor. Benzene was detected in concentrations up to 6,250 ppb. Exceedances of the screening level were detected in the Voluntary Evacuation Area and the Ceresco Area. The mobile field gas chromatograph was used and analyzed four samples in the Voluntary Evacuation Area during this timeframe with detections from 1.2 to 27.3 ppb recorded and no exceedances of the 60 ppb benzene screening level indicated (MI DCH 2014a). The results of the benzene monitoring during the Initial Response Period are shown in Table 7-4.

Table 7-4 Benzene Concentrations in ppb during the Initial Response Period

Hydrogen sulfide monitoring was also performed at these locations during these periods. A screening level of 70 ppb H_2S was established for this response. Of the four sampled areas, the screening level was only exceeded in the Voluntary Evacuation Area. During the initial response period one of four samples taken in the Voluntary Evacuation Area exceeded the screening level. (MI DCH 2014a). The results of the H_2S monitoring during the Initial Response Period are shown in Table 7-5.

Voluntary Evacuation Period (July 29 to August 17, 2010)

During the voluntary evacuation period 98 of 3,925 VOC measurements at all four locations indicated concentrations greater than 1,000 ppb screening level (MI DCH 2014a). The results of the VOC monitoring during the Voluntary Evacuation Period are shown in Table 7-6.

During the voluntary evacuation period, 64 of 2,591 samples collected using an UltraRAE real-time monitor indicated exceedances of the 60 ppb benzene screening level, with detections up to 2,200 ppb. The mobile field gas chromatograph analyzed 36 samples in the four areas during this timeframe with detections up to 17.6 ppb recorded and no exceedances of the 60 ppb benzene screening level indicated (MI DCH 2014a). The results of the benzene monitoring during the Voluntary Evacuation Period are shown in Table 7-7.

Post Evacuation Period (August 18 to December 31, 2010)

In the Post-Evacuation Period 25 of 11,252 VOC measurements exceeded the 1,000 ppb screening level. Higher readings during these periods were attributed to oil recovery activities along Talmadge Creek and at Ceresco dam. (MI DCH 2014a). The results of the VOC monitoring during the Post Evacuation Period are shown in Table 7-9.

A screening level of 6 ppb benzene was utilized by MI DCH in the Post Evacuation Period to indicate if long term chronic exposures may have resulted from the release. During the post evacuation period 27 of 7,377 samples collected using an UltraRAE real-time monitor indicated exceedances of the 6 ppb benzene screening level, with detections up to 9,450 ppb. The mobile field gas chromatograph was not used during this period (MI DCH 2014a). The results of the benzene monitoring during the Voluntary Evacuation Period are shown in Table 7-10.

Throughout 2011, no detectable concentrations were recorded associated with the pipeline release in a total of 3,146 VOC samples taken. No detections of

benzene were monitored in a total of 2,593 UltraRAE samples and no detections of H_2S were identified in 2,968 H_2S samples (MI DCH 2014a).

Rainbow Pipeline, Alberta, Canada: *On April 29, 2011, Plains Midstream Canada ULC (ERCB 2013) reported a pipeline failure which released 28,300 barrels of light sweet crude oil from their Rainbow Pipeline in Alberta. There were no residences within 12 km (7.5 miles) of the release point. A school located in Little Buffalo, 12 km from the release, was evacuated and closed voluntarily on April 29 as a precautionary measure. The school remained closed on the following Monday, May 3. Air monitoring was performed from May 3 to May 14 at the school. The monitoring indicated no evidence of substantive risk from airborne contaminants. Three additional sites were also monitored. No exceedances of ambient air quality standards were measured.*

Silvertip Pipeline, Laurel, Montana: *On July 1, 2011, the ExxonMobil Silvertip Pipeline carrying medium sour crude oil ruptured, releasing 1,500 barrels into the Yellowstone River in Laurel, Montana (USDOT 2012). The typical concentration of VOCs in this crude oil is 142 milligrams per kilogram (mg/kg) of benzene, 1,060 mg/kg of toluene, and 2,530 mg/kg of xylenes. Samples of weathered crude oil collected four days after the release indicated that the BTEX compounds were no longer detectable (USEPA 2011). However, there is no information available regarding VOC concentrations in air.*

Mid Valley Pipeline, Mooringsport, Louisiana: *On October 13, 2014, the Sunoco Logistics Mid Valley Pipeline ruptured near Mooringsport, Louisiana releasing 4,500 barrels of light sweet crude oil. Two residences adjacent to the spill were voluntarily evacuated. Air monitoring around the perimeters of the homes showed no detectable VOC concentrations in the air six days after the release, so the residents were allowed to return home on October 19 (USEPA 2014a).*

Yellowstone River, Glendive, Montana: *On January 17, 2015, Bridger pipeline released 715 barrels of Bakken light crude oil into the Yellowstone River five miles upstream of Glendive, Montana (MT DEQ 2015a). For the seven consecutive days after the release, ambient air quality sampling indicated no elevated levels of hydrocarbon components in the city of Glendive (USEPA 2015a).*

Marshall, Michigan, and Red Deer, Alberta: *Laboratory experiments were performed by Zhou et al. (2015) to evaluate the behavior of a conventional light crude oil release (Red Deer Alberta 2012) versus a diluted heavy crude oil (diluted bitumen) release (Marshall, Michigan 2010). The study shows that diluted bitumen products have lower BTEX contents than conventional light and medium crudes, which contain 2 to 4 vol % BTEX. The study states that the volatile fraction of the*

conventional light crude oil was 30 weight percent versus 13.3 weight percent for the dilbit.

The study also evaluated the rate of evaporative loss of the volatile fraction of both the dilbit and the conventional light crude oil based on the laboratory experiment. The majority (75 to 85%) of the loss occurred within the first six hours of the test. Further continued loss occurred over the following two to seven days.

The Red Deer release resulted in strong odors that lasted for several hours. At Marshall the odor persisted for a longer period, but that may have been due to the larger size of the release and the longer duration of the actual release. The author did suggest that a secondary consideration may have been the slower release of the volatile compounds from the dilbit (Zhou et al 2015).

***USEPA and U.S. Coast Guard – Bakken Crude**: The USEPA shipped 1,675 gallons of Bakken light crude oil to Eddystone, Pennsylvania for a pilot test, which was supported by the US Coast Guard. The study goals were stated to be (USEPA 2015b):*

1. *Evaluate benzene and other VOC emissions from a discharge of Bakken oil to gain more information to support Health and Safety decisions for responders and the public*
2. *Evaluate physical properties of Bakken oil, including weathering progresses, to better predict the fate on the surface water*
3. *Evaluate recoverability of fresh and weathered Bakken oil using standard methods*

On February 11, 2015, 660 gallons of crude oil shipment was discharged into a 100 ft by 65 ft outdoor test tank filled with water. The maximum ambient temperature during the study was 34°F. The oil was allowed to sit in the tank for 24 hours while air emission information was collected. The oil was then allowed to weather an additional week. Sampling of the oil indicated that within 24 hours all of the benzene evaporated from the oil sheen. Within six hours of the initial release, all VOC readings of the ambient air above the tank were below 5 ppm. USEPA estimated that 27% of the oil was lost to evaporation within the first 24 hours. After one week, 40% of the crude oil had been lost, with the majority of the loss being assumed to be evaporation.

7.1.2.1.2 Expected Effects of Released Oils

Key findings related to the potential effects of crude oil releases to air are presented below.

Table 7-12 and Table 7-13 provide a summary of the expected environmental effects of oil releases to air. Table 7-12 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-13 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

- Crude oil is a complex mixture of petroleum hydrocarbons. These hydrocarbons may contain only a few carbon atoms or contain 20 or more carbon atoms in long-chained, complex hydrocarbon molecules. In general, shorter and less complex hydrocarbons are more volatile, which means they evaporate more readily than longer chained hydrocarbons. These shorter chained compounds are referred to as VOCs.
- The release of VOCs, such as benzene, primarily occurs within the first 24 hours of an oil release.
- Since the rate at which the volatile organic compounds, such as benzene, evaporate from an oil release does not vary greatly, the actual concentrations observed in the surrounding community will be most affected by initial concentrations of benzene in the crude oil, the actual mass of oil released, the size of the area impacted by the release due to movement of the oil plume, and weather conditions, such as winds and atmospheric stability that will impact dissipation of the evaporated chemicals.
- The evaporative loss of longer chain petroleum hydrocarbons is controlled by weather conditions, such as wind and temperature and the depth of the pooled oil.
- The areas most affected by releases from a crude oil incident to the atmosphere are in the near vicinity of the oil release site or near areas of extensive recovery operations.

Table 7-12 Environmental Effects: Air Exposures

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil chemistry—volatile compounds and BTEX	Light crude oils contain 35 to 40 wt% volatile organic compounds (less than C10) (Crude Monitor 2016). The C2 to C4 organics are 3 to 9 wt% (NDPC 2016). The total BETX concentration of light crude is 2 to 4 Vol % (Zhou et al. 2015)	Medium crude oils contain 25 to 30 wt % volatile organic compounds (less than C10) (Crude Monitor 2016). The C2 to C4 organics are less than light crude oils. The total BTEX concentration of medium crude is 1 to 3 Vol % (Zhou et al. 2015)	Heavy crude oils contain 15 to 20 wt % volatile organic compounds (less than C10) (Crude Monitor 2016). The C2 to C4 organics are minimal. The total BTEX concentration of heavy crude is 0.5 to 1.5 Vol % (Zhou et al. 2015).	Diluted bitumens may contain variable amounts of BTEX, depending upon the characteristics and amount of the diluent used. For all of the crude oil types the benzene concentration represents 10 to 15 % of the total BTEX concentration (Crude Monitor 2016).
Oil chemistry—sulfur concentration	Light sweet crude oil contains less than 0.5 wt% Sulfur. Light sour crude oil contains 0.5 to 1.5 wt% Sulfur (Zhou et al. 2015). Bakken Crude oil contains less than 0.2 wt% Sulfur and less than 1 ppm H2S. (NDPC 2016)	Medium conventional crude oil contains 1.5 to 2.5 wt % Sulfur (Zhou et al. 2015).	Heavy conventional crude oil contains 3 to 5 wt % Sulfur (Zhou et al. 2015).	The sulfur content of diluted bitumens are similar to conventional heavy crude oil, but contains a relatively low level of H2S (Zhou et al. 2015).

Table 7-13 Environmental Effects: Air

Environment Characteristic	Low	Medium	High	Other Comments
Topographical change (terrain)	An oil release in a relatively flat area will result in pooling. The release of BTEX compounds is diffusion limited, so deeper pooling will slow the release of BTEX compounds, but also results in the compounds being released in a very localized area (Hanna and Drivas 1993).	As topography provides a means to move the oil release, the pooling of the crude oil will lessen. An increase in surface area does not significantly increase the oil evaporation rate (Fingas 1999), but the released compounds will be spread over a wider area.	See medium terrain effects.	
Flow velocity of the water body	An oil release into a slow moving water body, such as a lake, will result in a slower spread of the oil with a smaller area being directly affected relative to bodies of water with higher currents. Organic compounds evaporated from the release will be concentrated in a localized area.	An increase in the velocity of the affected water body will result in increased spreading of the crude oil. An increase in the surface area of the oil sheen does not significantly increase the oil evaporation rate (Fingas 1999), but the released compounds will be spread over a wider area.	See medium velocity effects. Higher velocity stream flows may also result in additional mixing, which would bring soluble constituents such as benzene into the water column, delaying the release of the benzene to the atmosphere.	The spread of petroleum released on water, including a waterbody with a slow to no current will generally be faster than the spread of a petroleum release on land.
Temperature	Low temperatures will mostly slow the volatilization rate of the heavier organic compounds (Fingas 1999). The light ends (C_2 to C_4 organics) will flash off readily as they are gases at lower temperatures and BTEX compounds will evaporate in the first 24 hours (USEPA study 2015, Zhou et al. 2015).	Heavier organic compounds will volatilize faster (Fingas 1999) in warmer temperatures, but the loss of light ends and BTEX are constrained by diffusion through the oil matrix, more than the increase in temperature (Hanna and Drivas 1993).	See medium temperature effects. High temperatures could lead to localized increases in ground-level ozone concentrations, but monitoring data has not shown any apparent increase based on case studies. (see Marshall case study).	

Table 7-13 Environmental Effects: Air

Environment Characteristic	Low	Medium	High	Other Comments
Distance to receptors	The potential effects to humans due to atmospheric concentrations of organic compounds are greatest near the release site and in areas of oil recovery activities. Voluntary evacuation orders were made for homes within 500 meters of Talmadge Creek (Marshall Case Study) and adjacent to the release in Louisiana (Mooringsport Case Study). The evacuation orders were lifted within one to three weeks of the release.	Odors and VOC concentrations were monitored two to six miles from the release site in the Squaw Creek subdivision and the village of Ceresco along the Kalamazoo River, but benzene alert levels were not exceeded (see Marshall Case Study). A school was voluntarily evacuated 7.5 miles from a release site, but real time air monitoring determined there was no substantive risk (Rainbow Pipeline Case Study).	VOCs were first detected at the Baker Estates subdivision in Battle Creek 3 days following the oil release. The subdivision is located ~15 miles from the original release location. No alert levels were exceeded (Marshall Case Study). Air monitoring performed in Glendive, Montana (5 miles upstream of a release) did not detect any VOC or benzene in the air for the 7 days following the release. (See Yellowstone River Case Study).	
Wind speed	Calm wind conditions will retard the evaporation of heavier volatile organic compounds (Fingas 1999). The evaporation rate of the more volatile organic compounds, such as benzene are unaffected by the wind conditions, so calm conditions and stable atmospheric conditions can result in the organic compounds being retained within the vicinity of the release site and can result in elevated concentrations.	A small increase in wind will allow mixing and increase the evaporation rate of the heavier organic compounds. Beyond the initial increase in wind from calm conditions to light, the volatilization rate of the organics is temperature related (Fingas 1999, Hanna and Drivas 1993). An increase in wind speed and instability will also increase the dissipation of volatile organic compounds, such as benzene and reduce ambient concentrations.	Heavy winds do not increase the volatilization rate of the heavier organic compounds from the crude oil matrix (Fingas 1999). Heavy winds will dissipate the volatile organic compound emissions, such as benzene, reducing ambient atmospheric concentrations.	

7.1.2.2 Groundwater

7.1.2.2.1 Description

Groundwater is water below the earth's surface that occurs in a porous or fractured geologic medium. The term groundwater is generally reserved for subsurface water that occurs beneath the water table and represents fully saturated geologic media (Freeze and Cherry 1979). However, the near surface partially saturated zone—referred to as the vadose zone—can be hydraulically connected to the underlying saturated zone and, as such, can play an important role in the discussion of potential groundwater effects from oil releases.

Groundwater is important as a water resource because of its significance as a source for domestic, agricultural, and industrial water supply, and its connection (source of recharge and discharge) to surface water bodies and natural surface water features (e.g., wetlands, fens, bogs, and marshes).

An oil pipeline release could potentially affect groundwater if the oil infiltrated into the soil and water soluble constituents in the oil partitioned into groundwater. If a sufficient volume of oil is released and the hydraulic pressure is sufficient to create a downward driving force, the oil in the pore space may infiltrate and reach the water table. Once in contact with the saturated zone, the vertical migration of the oil continues until buoyancy and increasing water content impede vertical migration. Water soluble compounds in the oil in contact with groundwater may form a dissolved-phase groundwater plume. If insufficient volumes and pressures of oil are present, the partially saturated vadose zone above the water table may hold oil in place and the released oil may never reach the water table. However, water soluble compounds may still dissolve into infiltrating pore water and may migrate to the water table. In general, sands and gravels allow for faster vertical migration of oil than less permeable soils composed of silts and clays.

Groundwater containing dissolved hydrocarbons may form an elongated plume in the direction of groundwater flow. Groundwater moves slowly, generally more slowly than water in rivers or streams. Groundwater flow rate is governed by the hydraulic gradient, and by the permeability of the medium and the effective porosity of the medium containing the groundwater (Freeze and Cherry 1979). In addition, natural attenuation processes such as retardation, biodegradation, and volatilization will limit the distance that dissolved phase constituents may migrate from the source of the oil release.

7.1.2.2.2 Observed Effects

Studies of crude oil and petroleum-related constituent releases provide a basis for evaluating the potential effects of crude oil releases on groundwater. A literature review was conducted to identify information on releases to groundwater. Following are the results of the review.

Most components of oils are relatively insoluble (Wang et al. 2003). However, oil in contact with groundwater will result in some dissolution of the soluble components. Generally, aqueous-phase

solubility decreases with increasing molecular mass (and size) of the hydrocarbon molecule (Rivett 2014). The relatively low molecular weight monocyclic-aromatic components of crude oil (BTEX) are some of the more water soluble hydrocarbon components of crude oil. Crude oil also contains PAHs, composed of between two and six fused benzene rings, often with alkyl side chains of one or more carbon units in length (i.e., alkylated PAHs). PAHs have moderate (e.g., naphthalene with two rings) to very low (e.g., 5- or 6-ring PAH molecules with alkyl side chains) solubility in water. The PAHs are considered to be toxic, and those PAHs having four or more benzene rings can also be carcinogenic. Therefore, the presence of PAHs can be a source of concern, even at low concentrations. Additionally, crude oil also contains heavy fractions that include waxes, asphaltenes, and nonpolar compounds, which are functionally insoluble in water, and may have limited bioavailability.

For those constituents that are relatively water soluble, the effective dissolved phase concentration is controlled by the concentration of the constituent in the oil and its solubility in water. It has been found that the maximum dissolved concentration of a constituent of oil in contact with groundwater is proportional to the mole fraction of the constituent in the oil (this is referred to as Raoult's Law), and as a result the individual constituents do not achieve the dissolved concentration in groundwater that might be expected based upon the solubility of the pure substance in water. Individual compounds are often more soluble in oil than in water, thus they tend to remain in the oil (O'Reilly et al. 2001). Additionally, because the most soluble components constitute a relatively small percentage of the overall mass of the oil, the effective soluble concentrations are relatively low. A study that compared the calculated dissolved-phase concentrations of 69 crude oils found that benzene was the only aromatic or PAH compound tested that is capable of exceeding groundwater protection values for drinking water (O'Reilly et al. 2001). Despite the relatively limited solubility of petroleum related constituents in groundwater, BTEX, and to a lesser degree PAH, dissolution remains one of the potential concerns of an oil release on groundwater.

MN PCA (2005) states that "[v]arious natural processes control the movement of a petroleum plume and act to limit the risk exposure. These processes include dispersion, sorption to soil particles, dilution, volatilization, natural biodegradation and natural chemical degradation. Of these processes, natural biodegradation through metabolism by naturally occurring microorganisms is the primary mechanism responsible for petroleum mass reduction. For most petroleum releases, natural biodegradation will reduce toxic chemical compounds to non-toxic metabolic byproducts". Numerous multi-site studies conducted since the 1990s have presented results that indicate dissolved-phase hydrocarbon plumes (primarily BTEX) stabilize at relatively short distances from the source area (Newell et al. 1990; Rice et al. 1995; Mace et al. 1997; Groundwater Services Incorporated 1997; Newell and Connor 1998; Ruiz-Aguilar et al. 2003; Kamath et al. 2012; Connor et al. 2015). Each of these studies indicated that dissolved-phase hydrocarbon plumes are unlikely to be greater than a few hundred feet in length. Newell and Connor (1998) presented a summary of four multi-site studies that evaluated the length of dissolved-phase BTEX plumes. Based upon the combined results of 604 sites, the median plume length was reported to be 132 ft, and 90% of the plumes were less than 319 ft in length. Similarly,

Connor et al (2015) presented a summary of 10 previous multi-site investigations in which plume length was evaluated for a total of 1,320 benzene plumes. Connor et al (2015) reported a median benzene plume-length of 140 ft and a 90th percentile of 345 ft at 772 sites delineated to 10 µg/L.

Of particular relevance is a study of 217 groundwater contaminated sites in Iowa that has similar surficial geology to that of the majority of the proposed pipeline routes, characterized by Quaternary glacial deposits (Ruiz-Aguilar et al. 2003). That study indicated mean plume lengths of 193 ft and 185 ft for dissolved benzene and toluene, respectively.

Studies of historical oil releases in Minnesota provide additional insight into the potential effects of oil releases on groundwater. The following provides a focus on a few cases with particular relevance to the conditions anticipated to be associated with the proposed pipeline.

> ***Bemidji, Minnesota****: Extensive studies of a release of crude oil near Bemidji, Minnesota, provided an in-depth understanding of the behavior of crude oil in a subsurface setting with similar geology and climate to sections of the proposed Project. The release has become known as the USGS Bemidji Crude Oil Research Site and is one of the most extensive research centers for land-based hydrocarbon releases. Researchers and regulatory agency personnel have agreed to limit remediation activities and to leave the remaining oil in place to study the effects of long-term natural attenuation processes. Research at Bemidji has involved extensive investigations of multiphase flow and transport, volatilization, dissolution, geochemical interactions, microbial populations, and biodegradation with the goal of providing an improved understanding of the natural processes limiting the extent of hydrocarbon contamination.*
>
> *On August 20, 1979, approximately 10 miles northwest of Bemidji, Minnesota, the land surface and shallow subsurface were contaminated when a crude-oil pipeline burst, releasing approximately 10,700 barrels of light crude oil (specific gravity 0.837 at 23°C; Baedecker et al. 2011) onto a glacial outwash deposit (Essaid et al. 2011). The site is located in the Bagley outwash plain near Bemidji, Minnesota. The surficial aquifer is approximately 60 ft thick and consists of sand and gravel outwash overlying till. Thin, discontinuous silt layers are inter-bedded with sand near the water table (Franzi 1988). The release occurred in the recharge area of a local flow system that discharges to a small closed lake approximately 1,000 ft hydraulically down gradient (Dillard et al. 1997). The burst section of pipeline was buried 5 to 10 ft below land surface, next to a railroad ROW, and approximately 15 ft above the water table. Locally, groundwater flows to the northeast with a mean groundwater flow velocity of approximately 300 ft per year (Bennett et al. 1993). Neither man-made hydraulic stresses (e.g., pumping wells and irrigation) nor other anthropogenic sources of the compounds of interest were present at the site at the time of the release.*

Clean-up efforts undertaken immediately following the release were able to recover approximately 75% of the released oil, and the remaining 25% is estimated to have infiltrated into the sand-gravel outwash aquifer forming three separate subsurface oil bodies (Essaid et al. 2011). Additional remediation activities during 1999 – 2004 removed a further 30,000 gallons of crude oil using a pump and skim remediation method (Enbridge 2008 in Essaid et al. 2011), but researchers requested that remediation be suspended to avoid interfering with ongoing research. Researchers and regulatory agency personnel have agreed to leave the remaining oil in place to study the effects of long-term natural attenuation processes.

Some crude oil infiltrated through the unsaturated zone to the water table near the rupture site and formed what is referred to as "the North pool." The separate-phase oil in the North pool was present within the sediment pore space from the land surface down through the unsaturated zone, and to 3 to 6 ft below the water table. Oil infiltrated through the unsaturated zone to form approximately a 5-ft thick zone containing separate phase oil at and below the water table. Some of the oil flowed over the surface toward a small wetland forming another oil-infiltration area (south oil pool). Oil saturations in the sediments (the volume fraction of pore space filled with oil) range from 10 to 20% in the unsaturated zone, to 30 to 70% near the water table (Dillard et al. 1997).

Spatial differences in the physical properties and degradation of the oil over time have caused alteration of the originally uniform source. The oil is selectively losing soluble and volatile compounds through dissolution and vaporization. Annual oil-mass loss rates of the crude oil source at different locations range from 0 to 1.25%, and total accumulated losses from the original oil mass are as much as 11% (Landon and Hult 1991). Dissolution of the free-phase oil into the groundwater has resulted in the formation of a plume of aliphatic, aromatic, and alicyclic (both aliphatic and cyclic) hydrocarbons. Infiltrated crude oil moved as a separate fluid phase approximately 100 ft in the direction of groundwater flow, while the plume of dissolved hydrocarbons in the groundwater extended up to 450 ft down-gradient from the leading edge of the source (600 ft in total; Cozzarelli et al. 2001). Most of the petroleum derivatives, including both aromatic and aliphatic compounds, migrating as solutes are actively being degraded by biologically mediated processes to carbon dioxide, water, and methane (Baedecker and Cozzarelli 1991).

An additional concern at the Bemidji site is the potential mobilization of naturally occurring heavy metals or trace elements such as arsenic. As a result of the geochemical and biochemical reactions occurring during the breakdown of hydrocarbons within the plume, studies have reported arsenic concentrations within the groundwater plume of 230 µg/L compared to less than 5 µg/L in

groundwater outside the plume (Cozzarelli et al. 2015). The arsenic was found to decrease down-gradient of the plume by re-attaching to the overburden solids through adsorption or co-precipitation with iron hydroxides, leading researchers to conclude that the breakdown of hydrocarbons alters the geochemistry of the area causing the release of arsenic from the overburden materials. Long-term monitoring of arsenic mobilization, as well as other naturally occurring heavy metals, is now occurring at the site.

The Bemidji site is in a remote area with sparse population. Therefore, the potential for harmful effects to groundwater used for water supply is low. Because of the large area over which the oil infiltrated the Bemidji aquifer, about 40% of the oil is trapped in the unsaturated zone, and a considerable volume of oil is in hydrodynamic equilibrium at the water table. Both the dissolved-phase plume and crude oil in the subsurface source have evolved over time as hydrocarbon compounds have degraded and dissolved at different rates (Landon 1993). Model results have also shown that compounds with high effective solubility (i.e., benzene) and/or rapid biodegradation rates (i.e., toluene) were more depleted in the oil body than heavier compounds (Essaid et al. 2003). The existing subsurface oil body remains source of hydrocarbon components that dissolve into and can be transported with groundwater. Nevertheless, the dissolved-phase plume at Bemidji site has stabilized at 450 ft long, predominantly due to biodegradation and spatial variability of site's hydraulic properties (Franzi 1988, Baehr and Hult 1991).

***Cass Lake, Minnesota**: An additional case study is available from a site near Cass Lake, Minnesota where a leak at a crude-oil pipeline pumping station resulted in subsurface infiltration of an estimated 1,150 barrels of crude oil to the water table, and development of a corresponding plume of dissolved constituents in groundwater. Unlike the Bemidji release, which occurred in a single incident more than 35 years ago, the Cass Lake release occurred as an ongoing leak over an unknown period of time, but may date back to when the pumping station began operations in 1971, ending after it was discovered in early 2002.*

The Cass Lake site is located approximately 25 miles from the USGS Bemidji, Minnesota, research site. The glacial outwash aquifer beneath the Cass Lake site constitutes part of the Bagley outwash plain. The aquifer consists primarily of moderately well sorted fine to medium grained sand and silt with some interbedded gravel. Grey calcareous clay-rich till underlies the aquifer approximately 25 to 45 ft below the land surface. The groundwater in the glacial outwash has a high horizontal hydraulic conductivity compared to the groundwater in the till (Drennan et al. 2010; Lohman 1972). Depth to the water table generally varies with topography and is roughly 25 to 30 ft below land surface (Wenck Associates 2006 in Drennan et al. 2010). Previous work indicated

that groundwater movement in the area is generally from northwest to southeast at a velocity of approximately 85 ft per year (Drennan et al. 2010).

A dissolved plume of benzene was estimated to extend approximately 500 ft to the southeast from the source. The dissolved plume is approximately 130 feet across and extends 6 to 10 ft vertically, with the location of maximum concentration becoming deeper with distance.

A monitoring program was established to define the extent of the contamination for the site and to verify human or ecological exposure. The remedial investigation included a review of all wells within a one mile radius of the site. The review concluded that no wells exist within 0.5 mile of the site in the direction the groundwater flows, 0.5 miles being greater than 5 times the estimated extent of the plume. Therefore, no humans have been exposed to any site contamination. Monitoring wells remain in place to detect if any contamination is moving toward any water wells. The monitoring also shows that the contamination is not entering a surface water body. The nearest potential surface water is Spike Lake, 0.5 mile away, well beyond the limits of contamination.

The USGS began a research project at the site in 2007 (Drennan et al. 2010). The research is focused on the natural attenuation and biodegradation of petroleum constituents in groundwater. As part of the USGS research, additional monitoring wells were installed specifically to monitor the natural attenuation of the dissolved groundwater plume in the down gradient direction. In 2010, the USGS published "U.S. Geological Survey Scientific Investigations Report 2010-5085: Fate and Transport of Petroleum Hydrocarbons in the Subsurface near Cass Lake, Minnesota," which details the results of the 2007 research project (Drennan et al. 2010).

The small area of the Cass Lake site leak presumably resulted in oil in hydrostatic equilibrium at the water table and with a minor amount of oil in the unsaturated zone. The progression of biodegradation of oil proceeds in a quasi-sequential manner with easily degradable compounds being lost first, but more resistant classes of compounds begin degrading before complete loss of less-resistant compounds. Data for the Cass Lake site oil samples show near complete depletion of the n-alkane fraction, placing the oil in the category of "heavily degraded" (Drennan et al. 2010). The alkyl-cyclohexanes are only partially degraded, indicating that the oil has not yet reached the category of "severely degraded." As oil degradation proceeds through higher levels of severity, the soluble fraction decreases to the point where very little dissolution of compounds into the groundwater occurs. Once the oil reaches this degradation state, at an unknown time in the future, the groundwater plume is not expected to pose a risk for further expansion. In the long term, a residual fraction of heavily degraded oil

> *consisting mainly of an unresolvable complex mixture of compounds will remain in the aquifer.*
>
> *The highly degraded state of the Cass Lake oil represents one of the important findings of the study. Although the start date of the Cass Lake leak is unknown, the highly degraded nature of the Cass Lake oil suggests the leak was active for decades. The Bemidji release is known to have occurred on August 19, 1979. After more than 30 years, the released oil in some locations is less degraded than the Cass Lake samples. Three possible aspects of the Cass Lake release that may contribute to the highly degraded state of the Cass Lake oil are: (1) the leak was active for many years, (2) high recharge rates stimulate degradation, and (3) the leak occurred slowly. The geochemical and microbial data show the redox conditions are similar to the Bemidji plume, which is decades old. Thus, the Cass Lake oil leak may have been present since the pumping station first began operations in 1971.*

7.1.2.2.3 Expected Effects of Released Oils

The potential effects of crude oil releases on groundwater include infiltration of residual oil into the vadose and saturated zones. The infiltrated oil may serve as a source of dissolved-phase volatile organic compounds in groundwater which in addition may alter the geochemical character of groundwater facilitating the increased dissolution of metals and other trace elements. The potential for releases to adversely affect groundwater quality depends upon multiple factors, including hydraulic gradient, soil type, geology, seasonal conditions, oil type, and the water solubility of constituents in the oil.

When crude oil is released to the ground, it needs to displace an equivalent volume of the resident fluids (air and/or water) from the soil. To infiltrate and enter a pore space it must overcome both the capillary pressure and the hydrostatic pressure needed to displace water (referred to as pore entry pressure). The ability of the oil to enter the pores is largely a function of the pressure of the release, properties of the geologic media, and density and viscosity of the oil (ITRC 2009). If a sufficient volume of oil is present overlying a porous media, it begins to enter the unsaturated pore spaces by moving downward under the force of gravity. This can be accompanied by lateral spreading due to geologic heterogeneity. Such liquids must have a sufficiently low viscosity to move through the local surface soils and overburden to reach the groundwater.

The percentage of oil held in pore space by the formation is referred to as "residual saturation." Oil at residual saturation is functionally immobile. It is in a state where additional movement is not anticipated because the forces of gravity are balanced by the capillary pressure. The oil distribution following gravity drainage from pores is characterized by an irregular, heterogeneous distribution of disconnected ganglia. Because a small amount of oil is retained in the pore space, the ability of the crude oil to reach the groundwater is a function of the vertical distance

that the oil must travel. The residual oil in the pore space may come in contact with infiltrating water and become a source of a dissolved-phase contaminant plume.

In the case of crude oil, which is less dense than water, downward migration continues through materials that are partially saturated with water until it reaches the water table. This impedes its migration deeper due to both increasing water content and associated buoyancy forces arising from the oil-water density contrast. Near the water table crude oil and water coexist in pore space as a smear zone and the vertical equilibrium distribution is determined by capillary pressure. The magnitude of lateral spread of oil near the water table is determined principally by the subsurface geology, size of the release, as well as the properties of the crude oil (e.g., density and viscosity) (Rivett 2014).

The mobility of oil in the unsaturated zone depends primarily on several factors: (1) its saturation in the pore space relative to the other fluids, (2) the pressure (matric potential) that drives the flow of oil (driving head); (3) the vertical permeability of the unsaturated soils; and (4) the physical properties of the oil (largely viscosity and density).

The horizontal flow velocity in groundwater is a function of fluid physical properties (e.g. viscosity), the groundwater pressure gradient, and hydraulic properties of the porous media (Freeze and Cherry 1979). The equation for flow velocity (Darcy's law) may be written as follows:

$$v = k\,\mathbf{d}P/\mathbf{u}\,\mathbf{d}x$$

Where:

v = fluid flow velocity
k = intrinsic permeability of the media
dP = the applied pressure difference
dx = the thickness of the porous media
u = viscosity

Factors that modify the behavior of crude oil releases with respect to groundwater contamination include soil type, hydraulic pressure, and crude oil properties, especially the amount and solubility of BTEX compounds. More permeable soils, such as sand and gravel, will allow for relatively faster infiltration and lateral migration of crude oil than less permeable soils, such as silt and clay. Coarse-grained soils would more readily admit or absorb released oil and, therefore, would be more prone to the development of persistent hydrocarbon plumes or free product. Increased hydraulic pressure results in increased gradients and faster flow velocity. Crude oils with low viscosity would also be more readily absorbed by soils and have greater potential to reach the water table.

Because both water and oil move slowly in the pores between soil grains, the distance between the ground surface and the water table (i.e., the depth to the water table) will also affect whether the oil reaches the water table, and the time it takes to get there. Thick unsaturated

zones (greater depths to the water table) may act as a "sponge" to hold crude oil in place, more so than thin unsaturated zones with less pore volume storage. In situations where a small amount of oil is released, the soils are less permeable, or where the water table is very deep, oil may remain in the unsaturated zone and never reach the water table. At some time following termination of the release, the oil will reach a hydrostatic equilibrium and be functionally immobile (ITRC 2009). At that point dissolution and volatilization cause gradual depletion of lighter crude oil constituents, which may be accelerated by local dissolved-phase plume biodegradation (Rivett 2014). The degradation of the oil body may be relatively slow. As described in the Bemidji and Cass Lake releases, more than 30 years following the releases, oil and groundwater plumes remain in the subsurface (Essaid et al. 2011; Drennan et al. 2010).

Dissolved hydrocarbons may enter the groundwater through preferential dissolution of the soluble constituents. Light oils also typically contain higher levels of the more water soluble hydrocarbons, such as BTEX, and this also would tend to increase the potential for the development of groundwater contamination. Benzene is the primary constituent of crude oil that is capable of exceeding drinking water standards in groundwater (O'Reilly et al. 2001). Dissolved hydrocarbon plumes may move laterally; however, the lateral distance traveled is relatively short, generally less than a few hundred feet, and balanced by natural attenuation processes that reduce the concentration in groundwater over time. Natural attenuation will transform most toxic constituents of petroleum releases into non-toxic metabolic byproducts, typically carbon dioxide and water (MN PCA 2005). Numerous multi-site studies conducted since the 1990s have presented results that indicate dissolved-phase hydrocarbon plumes stabilize at relatively short distances from the source area and are unlikely to be greater than a few hundred feet in length (Newell and Connor 1998; Connor et al. 2015). The groundwater plumes resulting from the Bemidji and Cass Lake releases are reported to have traveled a maximum distance of approximately 450 ft and 500 ft, respectively.

Oil releases that affect the groundwater may also change the groundwater geochemistry as the hydrocarbons undergo biodegradation. The microbial degradation of hydrocarbons consumes oxygen and affects the reduction-oxidation (redox) state of other substances, such as sulfate, iron, and manganese present in the subsurface environment. Such redox reactions can transform iron and manganese from solid to soluble phases, and, in the process, release other trace elements that were previously bound by or co-precipitated in the solid phase. Arsenic concentrations within the hydrocarbon plume at the Bemidji site have been reported to be significantly higher than background concentrations and exceed drinking water standard, as the chemical reactions within the plume have caused arsenic to mobilize and leach out of the overburden solid phase (Cozzarelli et al. 2016). Arsenic is naturally present in soils and sediments, but is not usually a health concern unless it is mobilized by a chemical reaction and dissolves into groundwater. Arsenic released in the hydrocarbon plume is expected to reattach to aquifer sediments down-gradient from the plume, limiting the extent of the arsenic contamination in the groundwater to the approximate extent of the dissolved phase plume (Cozzarelli et al. 2016).

Key findings related to the potential effects of crude oil releases to groundwater are presented below.

- A crude oil release could potentially affect groundwater if the oil infiltrated into the soil and water soluble constituents in the oil partitioned into groundwater.
- Specific environmental conditions must be met to allow for the soluble components to reach the groundwater. The ability of a crude oil or the soluble components of crude oil to reach the groundwater is influenced by the depth to groundwater, geologic material permeability, and recharge.
- The ability of a crude oil to migrate vertically through a soil column is also influenced by the crude oil properties and release characteristics: hydraulic pressure, crude oil viscosity, crude oil density, and time.
- Dissolved hydrocarbons may enter the groundwater through preferential dissolution of the soluble constituents with benzene being the primary constituent of crude oil that is capable of exceeding drinking water standards in groundwater.
- Dissolved hydrocarbon plumes may move laterally in the direction of groundwater flow; however, the lateral distance traveled is relatively limited (generally less than a few hundred feet) and balanced by natural attenuation processes that reduce the concentration in groundwater over time and with travel distance in the aquifer.
- Crude oil releases that affect the groundwater also have the potential to change the groundwater geochemistry as the hydrocarbons undergo biodegradation. Redox reactions can transform iron and manganese from solid to soluble phases, and, in the process, release other trace elements, such as arsenic, that were previously bound by or co-precipitated in the solid phase. However, such trace elements are also likely to be removed from the dissolved phase and return to the solid phase once the groundwater emerges from the influence of the dissolved hydrocarbon plume.

Studies show that groundwater plumes of hydrocarbon compounds can persist for many years following a release of crude oil. Residual crude oil has the potential to serve as a source of dissolved phase contaminants in groundwater at concentrations above drinking water standards. However, the effects are generally restricted to low molecular weight hydrocarbons such as the BTEX compounds, and are limited to a relatively small area proximal to the release.

Table 7-14 and Table 7-15 provide a summary of the expected environmental effects of oil releases to groundwater. Table 7-14 considers the effects of specific oil characteristics or oil type on the expected type and scope of environmental effects. Table 7-15 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-14 Environmental Receptor: Groundwater

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil chemistry—soluble constituents	Light crude oils often contain relatively higher levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, depending on the oil type, but can be high (>10,000 mg/kg) in Bakken oils.	Medium crude oils often contain moderate levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, but can exceed 10,000 mg/kg.	Levels of BTEX and other relatively water soluble constituents are variable: generally low in heavy conventional oils, but variable in diluted bitumens depending upon the nature of the diluent. Levels of TPAH are variable, but typically depleted in napthalene and less than 10,000 mg/kg.	Regardless of the specific ratio of soluble constituents in the oil chemistry, benzene is the primary constituent that is typically capable of exceeding drinking water standards in groundwater (O'Reilly et al. 2001). The length of dissolved constituent plumes in exceedance of drinking water standards are generally less than a few hundred feet from the release location.
Oil properties—viscosity	Light crudes exhibit lower viscosity (1 to 5 mPa•s; NAS 2015). As a result of the lower viscosity, light oils are capable of infiltrating into soils at a relatively faster rate than higher viscosity oils.	Medium crudes have an intermediate viscosity (8 to 112 mPa•s; NAS 2015).	Heavy crudes (820 to 475,000 mPa•s) and diluted bitumens (270 to 50,000 mPa•s) weather to high viscosity (NAS 2015). The viscosity of fresh diluted bitumen is reduced by the addition of diluent, to conform to pipeline specifications.	The ability of oil to be transmitted through permeable media is inversely proportional to its viscosity. Viscosity is a function of oil chemistry. Diluted bitumens tend to display a more rapid increase in viscosity due to weathering than conventional heavy crude oils as a result of the rapid initial evaporation of some of the diluent. Viscosity also affects the residual saturation (amount of oil held within the formation). Residual saturation increases with viscosity. Recovery of released oil is facilitated if the oil is less dense and, as a result, exhibits a lower residual saturation.

Table 7-14 Environmental Receptor: Groundwater

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—density	Light crude oils typically have a low relatively specific gravity (0.78–0.88 g/mL, (Dupuis and Ucan-Marin 2015). The ability of the oil to enter the pores of a geologic medium is affected by density (ITRC 2009). Less dense fluids would be anticipated to infiltrate at a lower rate (all other factors being equal). In addition less dense fluids that migrate to the water table may spread more and penetrate the water table less due to the buoyancy effect caused by the density difference between water and oil.	Medium crude oils typically have an intermediate specific gravity compared to light and heavy crudes (Dupuis and Ucan-Marin 2015).	Heavy conventional crude oils can have density ranging of 0.88 to 1.00 g/mL, while fresh diluted bitumen will have a density less than 0.94 g/mL, increasing towards a density of 1.00 g/mL or slightly higher when fully weathered (Dupuis and Ucan-Marin 2015).	Density is directly proportional to the ability of the oil to move through a permeable material. An oil release with a relatively low density will travel faster in the subsurface than a relatively denser fluid. In addition the buoyancy will influence the distribution of oil at the soil water interface with less dense oils accumulating closer to the top of the water table and extending further into the capillary zone. Density and viscosity are correlated, so low density oils also tend to have low viscosity, whereas oils having higher density tend to have higher viscosity. High density slightly increases the ability of crude oil to flow within the overburden, but not to the extent that the higher viscosity is limiting the potential for movement.

Table 7-15 Environmental Receptor: Groundwater

Environmental Characteristic	Low	Medium	High	Other Comments
Soil permeability	Less permeable soils, such as silt and clay, will allow for relatively slower migration of crude oil than more permeable soils.	Medium-grained soil (fine sand to coarse sand) will allow for moderate oil infiltration	More permeable soils, such as sand and gravel, will allow for relatively faster migration of crude oil than less permeable soils.	Coarse-grained soils would more readily admit spilled oil, and, therefore, would be more prone to the development of persistent hydrocarbon plumes or free product. It is also noted that shallow bedrock exhibits a unique environment where permeability may be relatively low but isolated fractures may allow crude oil to be transported relatively quickly through preferential flow pathways.
Depth to groundwater	Thin unsaturated zones with less pore volume storage are more susceptible to oil migrating to the water table and potentially impacting groundwater resources.	Moderate unsaturated zones are relatively less susceptible than thin unsaturated zones.	Thick unsaturated zones are less susceptible to oil migrating to the water table. In situations where a small amount of oil is released or the water table is very deep, oil may remain in the unsaturated zone and never reach the water table.	Because both water and oil move slowly in the pores between soil grains, the distance between the ground surface and the water table (i.e., the depth to the water table) will affect whether the oil reaches the water table, and the time it takes to get there. Unsaturated zones may act as a "sponge" that hold crude oil in place. In situations where a small amount of oil is released or the water table is very deep, oil may remain in the unsaturated zone and never reach the water table.

Table 7-15 Environmental Receptor: Groundwater

Environmental Characteristic	Low	Medium	High	Other Comments
Weather conditions—temperature	Light oils remain fluid at lower temperatures and retain the potential to spread rapidly during the winter. In summer, light crude oils would also flow readily, having a greater potential to infiltrate more quickly than more viscous heavier oils.	Medium oils are slightly more viscous than light oils, and would also tend to flow readily under winter conditions. Medium crude oils would tend to flow readily under summer conditions.	Heavy oils become much more viscous at low temperatures, and as they weather. Heavy oils and diluted bitumens would have more resistance to flow than would be the case for light or medium crude oils. During the summer, diluted bitumens would flow readily.	Temperature affects both the behavior of oil in the environment, and the rate of natural attenuation processes such as volatilization and biodegradation. Key physical properties of oil such as viscosity may be sensitive to temperature. In addition, temperature plays an important role in biodegradation of hydrocarbons by affecting the physiology and diversity of the microbial community. Winter conditions such as frozen ground may greatly reduce the surficial permeability of soils inhibiting the vertical migration to groundwater.
Organic carbon content	Geologic media with low organic carbon content (e.g., clean sands and gravels) may be more prone to larger dissolved phase plumes because the constituents are not retarded by the adsorption/desorption processes.	NA	Soils containing abundant organic carbon (e.g., near surface soils and peats) may retard the transport of petroleum constituents in the subsurface.	Organic carbon can retard transport of dissolved petroleum hydrocarbon constituents reducing the potential overall distribution of these constituents in groundwater.

Table 7-15 Environmental Receptor: Groundwater

Environmental Characteristic	Low	Medium	High	Other Comments
Geochemistry	A relatively low quantity of electron acceptors such as oxygen, nitrate, iron or sulfate may limit the biodegradation processes. A low concentration of metals will limit the potential mobilization of metals in groundwater.	Moderate geochemistry is relatively less amenable to biodegradation and less susceptible to mobilization of metals than zones with an abundance of electron receptors and available metals.	An abundance of electron receptors within the dissolved plume may promote biodegradation processes. A high concentration of heavy metals and trace elements, such as arsenic, may support the potential mobilization of these constituents in groundwater.	The natural geochemistry of groundwater may influence both the natural attenuation processes and the potential dissolution of metals. Many indigenous microorganisms in groundwater and soil are capable of degrading hydrocarbon contaminants; however, this process may be rate limited by the presence of electron acceptors. The infiltrated oil may alter the geochemical character of groundwater, facilitating the increased dissolution of potentially toxic heavy metals and other trace elements such as arsenic.
Local recharge—rainfall	Low recharge will retard or delay the infiltration of soluble oil constituents towards the groundwater table, and into the groundwater.	N/A	High recharge will accelerate the infiltration of soluble oil constituents towards the groundwater table, and into groundwater.	Periods of high rainfall and high water levels could increase dissolution of soluble components of crude oil and facilitate transport to groundwater, while also reducing the time available for oil spill response activities to prevent environmental effects on groundwater quality.

Table 7-15 Environmental Receptor: Groundwater

Environmental Characteristic	Low	Medium	High	Other Comments
Release properties—driving head	The ability of an oil to penetrate a permeable geologic media is partially a function of the driving head (matric potential) exerted by the oil. A relatively small driving head would result in a low infiltration rate, all other factors being equal.	N/A	The ability of an oil to penetrate a permeable geologic media is partially a function of the driving head (matric potential) exerted by the oil. A relatively large driving head would result in a high infiltration rate, all other factors being equal.	Fluid flow velocity in a permeable media is governed by Darcy's law which relates velocity to intrinsic permeability, porosity, and applied pressure. The fluid velocity is directly proportional to the applied pressure.
Release properties—time	The volume of oil able to penetrate the subsurface is related to the rate of infiltration and time. A short time to spill response would be expected to result in a relatively smaller volume of oil in the subsurface, and lower potential for effects on groundwater.	N/A	A long time to spill response would be expected to result in a relatively larger volume of oil in the subsurface, and greater potential for effects on groundwater.	The volume of oil able to migrate vertically through a soil column is influenced by the oil infiltration rate and time. The oil volume able to penetrate the subsurface is directly proportional to the time the oil remains in contact with the geologic media. A quick and effective response to an oil release will minimize the potential for adverse effects on groundwater.

7.1.2.3 Lakes

7.1.2.3.1 Description

Lakes are defined as permanent standing water bodies surrounded by land. The water is typically fresh, although occasionally (usually in arid areas) it can be brackish or saline. Lakes may transition to wetland areas such as bogs, marshes, fens or swamps, but are differentiated by having predominantly open water, not occupied by vegetation. Such wetland areas are often peripheral or adjacent to lakes. Lakes may also transition into slowly moving river areas and can be differentiated on the basis of whether factors dominating flow are hydraulic (i.e., rivers) or wind and thermal circulation (i.e., lakes). Lakes are included in the effects assessment of land cover receptors due to their importance to aquatic and terrestrial life. They provide habitat for fish, amphibians, plants, benthic invertebrates, insects, birds, and mammals.

The effects assessment for lakes focuses on physical and chemical effects (i.e., habitat and water quality) of released, and excludes direct effects of oil on aquatic biota (e.g., aquatic plants, fish, wildlife) or sediment quality, which are considered elsewhere. Crude oil that enters a lake will generally float on the water surface. However, oil can also enter the water column as dissolved hydrocarbons or as liquid hydrocarbon in forms that range from small droplets suspended in the water column, to larger globules or other forms of oil that may re-surface, remain suspended in the water column, or sink to the bottom (Hollebone et al. 2011). Relevant petroleum exposure monitoring parameters in water include benzene, toluene, ethyl benzene and xylene (BTEX, low molecular weight and relatively volatile and water-soluble fractions that weather and biodegrade quickly), polycyclic aromatic hydrocarbons (PAHs, more persistent substances composed of two or more fused benzene rings, which are more often implicated in chronic environmental effects of hydrocarbons) and aliphatic hydrocarbons (hydrocarbon molecules that are composed of more linear, although often branched, chains of carbon atoms). More general monitoring parameters include "total" or "extractable" petroleum hydrocarbon (TPH/EPH).

7.1.2.3.2 Observed Effects

There is potential for oil released accidentally from a pipeline to reach a lake proximal to, and downgradient from, the pipeline corridor. However, releases directly to a lake appear to be rare, given that pipeline routes typically avoid lakes. A more common scenario is for oil to enter a stream or river, and then move downstream to a lake. This is supported by the literature on oil releases. Discussions of four case studies with circumstances similar to those that might be encountered in the event of an oil release from a pipeline in Minnesota are presented below.

> ***Wabamun Lake, Alberta:*** *On August 3, 2005, a train belonging to Canadian National railways derailed, releasing approximately 4,500 barrels of Heavy Fuel Oil 7013 (a Bunker C type fuel oil with a high viscosity and an initial density of about 0.99 at lake temperature) and 553 barrels of pole treating oil (Transportation Safety Board of Canada 2007). About 20% of the released heavy fuel oil*

(950 barrels) traveled overland and entered Wabamun Lake. No appreciable volume of pole treating oil entered the lake (Hollebone et al. 2011).

In the lake, the oil floated and spread rapidly over the lake surface. After a few days, strong winds and wave action dispersed the oil toward the northern, eastern, and southern shorelines, where it became entrained in macrophyte beds (Thormann and Bayley 2008; Anderson 2006). The windy conditions also resulted in mixing of the oil in the water column, with PAH and BTEX concentrations initially higher in boomed areas than Canadian water quality guidelines for protection of aquatic life, but lower than the guidelines in open water areas outside the boomed areas (Anderson 2006). While traveling overland, the oil mixed with soil and organic matter, and in the lake, OPAs formed quickly, including small tar balls, larger balls called "tar logs," submerged sheets, and large lumps. The composition of the aggregates was not static, and tar balls sometimes reformed into oil slicks (Fingas et al. 2006; Hollebone et al. 2011). The aggregates showed a variety of behaviors, including submergence, neutral buoyancy, and resurfacing (Fingas et al. 2006), with extensive tar mat formation in some nearshore areas. Behavior of oil in the lake (rapid formation of tar balls, sinking, slow degradation due to high proportions of high molecular weight components such as resins) and toxicity and persistence due to high PAH levels but low BTEX levels, was related to characteristics of the heavy fuel oil. Within four months of the release, concentrations of BTEX and PAHs were below detection in lake water (Birtwell 2008; Anderson 2006).

High initial density and viscosity, and a lack of lower molecular weight components in the heavy fuel oil distinguish this released oil from the types of crude oil and diluted bitumen products expected to be transported in the proposed pipeline.

***Marshall, Michigan:** On June 25 and 26, 2010, the Line 6B pipeline owned and operated by Enbridge ruptured, releasing approximately 20,000 barrels of heavy crude oil (NTSB 2012a). Of the released oil, approximately 8,200 barrels entered Talmadge Creek, a tributary to the Kalamazoo River, near Marshall, Michigan (NTSB 2012a). The released oil was a combination of Western Canadian Select and CLB diluted bitumens. The release occurred on the floodplain of Talmadge Creek, where wetlands are abundant (USFWS et al. 2015a). Some of the released oil traveled down Talmadge Creek to the Kalamazoo River.*

The Kalamazoo River is a meandering, low gradient river with diverse channel and floodplain features, extensive floodplain forests and wetlands, off-channel water bodies, and impoundments (Dollhopf et al. 2014). Upon entering the water, the density of the crude oil was less than that of water, and it floated, forming an oil slick that flowed downstream. The Kalamazoo River was in flood at the time of

the release, and oil was carried as far as Morrow Lake, an impoundment in the river, 36.5 miles downstream. Oil was deposited on river shoreline, riparian, and depositional areas, and also along the shores at the delta of Morrow Lake (USFWS et al. 2015a).

High river flows entrained some of the oil into the water column (resulting in submerged oil). Dam spillways may also have caused emulsification of some of the oil, and driven further oil into the water column. Over time, weathering of the lighter components and interaction of the submerged oil with suspended or shoreline/bottom sediments resulted in some of the oil sinking to the river bed in slow-moving or depositional areas of the river, particularly the upper end of Morrow Lake, a lake-like impoundment in the river. Formation of OPAs was likely promoted by the flood conditions at the time of the release, which increased turbulence and suspended sediment loads in the river, and by the turbulent mixing of water and oil (Fitzpatrick et al. 2015). The oil that reached Morrow Lake had been pre-conditioned by river transport (weathering, formation of OPAs) prior to reaching the lake.

Surface water was sampled from July 2010 through April 2012 and measured for oil-related and non-oil related chemicals. Only a very few of these measured chemicals were detected above health-protective screening levels and most of the chemicals detected at these levels were PAHs (MI DCH 2014b). It was not expected that people would be exposed to levels of these chemicals that would cause long-term health concerns.

Oil was deposited on sediments in the delta of Morrow Lake, and subsequently removed during clean-up activities.

Red Deer River, Alberta: *On June 7, 2012, approximately 2,900 barrels of light crude oil was released from a ruptured pipeline owned and operated by Plains Midstream Canada ULC, into Jackson Creek, a tributary of the Red Deer River, about 1.9 miles north of Sundre, Alberta. Floodwaters 10 times higher than the typical June flows eroded the stream bed and banks, and exposed the pipeline under the river, which then ruptured (Alberta Energy Regulator 2014). Oil travelled at least 25 miles downstream to Gleniffer Lake reservoir, where booms contained the floating oil. Dissolved hydrocarbons in river water were detected up to 5 miles further downstream during the first week post-release (Alberta Environment and Sustainable Resource Development [ESRD] 2012a).*

Hydrocarbon (BTEX, PAH, and alkanes) concentrations in water were monitored twice a day in the first week post-release, then once a day to July 12, 2012 (Alberta ERSD 2012b). Lighter weight hydrocarbons (BTEX) evaporated quickly, but some dissolved in the river water and, in the early days post-release, were

detected up to 30 miles downstream of the release location. One day post-release, benzene and toluene were detected in Gleniffer Lake, with toluene (peak of 0.0314 mg/L near the booms) above the Canadian water quality guideline for aquatic life (0.002 mg/L). BTEX and PAHs attributable to the release were detected up to nine days post-release. PAH concentrations also decreased over time and were below Canadian water quality guidelines for protection of aquatic life on all dates, except for benz(a)anthracene at three times the guideline four days post- release at several locations in Gleniffer Lake.

The main concerns for Gleniffer Lake and downstream areas were for drinking water quality, but monitoring indicated no detectable hydrocarbons in drinking water intakes (Alberta ERSD 2012b). Reports of habitat studies in Gleniffer Lake were not found. The lack of studies is likely due to concerns about lake habitat being reduced because of the low volume of the release in proportion to the volume of river (large dilution) and the high amount of weathering, related to both distance (25 miles) and type of oil released (light crude oil) upstream of Gleniffer Lake. No reports were found of oil sinking in the river or Gleniffer Lake.

Unamed Lake, Alberta: *On June 22, 2013, a break in Line 37, the Line 37 pipeline owned and operated by Enbridge Pipelines Inc., resulted in release of 1,300 barrels of synthetic light crude oil onto the pipeline ROW. The oil traveled overland to a fen, then reached a small, unnamed lake. Physical barriers were deployed to limit spreading of the oil. As part of the subsequent site assessment and remediation process, total of 137 sediment samples were collected from 64 locations between July and August, 2014. In sediment, the highest petroleum hydrocarbon concentrations were found along the northwest shoreline of the lake. Targeted sediment excavation occurred in the northwestern portion of the lake where the highest hydrocarbon concentrations were observed close to shore (Hemmings et al. 2015).*

Mayflower, Arkansas: *On March 29, 2013, a breach in the 20-in. Pegasus Pipeline operated by the ExxonMobil Pipeline Company released crude oil into a residential neighborhood in Mayflower, Arkansas (Arcadis 2014). The crude oil was identified to be Wabasca heavy crude oil (a type of diluted bitumen originating from Alberta, Canada). An emergency response action was implemented to mitigate the release, resulting in the recovery of a substantial amount of the crude oil. From the residential area, some of the oil entered a drainage way leading to a shallow drainage swale along North Main Street. From there the oil flowed east under Highway 365 and Interstate 40 (I-40) into a marsh known as Dawson Cove (Figure 1-1). Dawson Cove is separated from Lake Conway by Highway 89, with water conveyed between the cove and lake by two culverts beneath the highway (Arcadis 2014).*

Sediment samples (including both surface and subsurface samples) were collected at 53 locations within the drainage ways, Dawson Cove, and Lake Conway. Background sediment samples were collected from six distant locations in Lake Conway upstream of the generalized flow path from Dawson Cove to the Lake Conway dam and six locations in shallow ditches upstream of the primary drainage path from the residential area to Dawson Cove. A total of 125 sediment samples were collected at 34 locations in Dawson Cove. Based on the screening results, hydrocarbon concentrations in 118 of 125 sediment samples were found to be at levels that did not require further evaluation (Arcadis 2014). Seven samples had xylenes and/or isopropylbenzene above the ESV; a refined risk evaluation, indicated that at the reported concentrations, no adverse effects were anticipated for aquatic life in Dawson Cove sediment (Arcadis 2014). A total of 18 sediment samples were collected at 6 locations in Lake Conway. Based on the screening results, sediments in Lake Conway did not warrant further evaluation (Arcadis 2014).

7.1.2.3.3 Expected Effects of Released Oils

The expected effects of crude oil released into a lake are changes in water quality and effects on physical habitat quality. The further effects of these changes on sediment quality and biological components of the aquatic environment (such as fish and wildlife) are discussed elsewhere. Most crude oils float on water (i.e., they have an initial density that is less than the density of fresh water). This applies to light crude oils such as Bakken oils, as well as to heavy crude oils such as diluted bitumens, which are generally limited to a maximum density of 0.94 when shipped by pipeline. While raw bitumen may have a density that is greater than 1.0, raw bitumen would be far too viscous to pump through a pipeline. It has been suggested (NAS 2015) that diluted bitumen could weather rapidly after being released, so that changes in its properties could result in sinking. However, Lee et al. (2015) concluded that "the observation of evaporative mass losses of less than 20% after rigorous weathering at environmentally-relevant temperatures for dilbits nominally comprising greater than or equal to 30% diluent suggests that a substantial proportion of diluent remains intimately associated with bitumen". Therefore, diluted bitumen is unlikely to weather naturally to a density greater than that of fresh water within a timeframe that is relevant to oil spill emergency response operations.

A release of fresh diluted bitumen is expected to result in effects similar to those for other heavy crude oils. Diluted bitumen does not completely separate into diluent and bitumen components when released (Taylor et al. 2014; Zhou et al. 2015; Fingas 2015a). Diluted bitumen floats on water and can be stranded on shorelines. Released oil can pick up soil and organic matter from land or water, and then form OPAs, which can sink if sufficient amounts of particulate matter are incorporated in the oil particulate aggregates. A high proportion of diluent (e.g., condensate) will evaporate quickly and some will be dissolved in the water column. The residual oil components (PAHs, heavier alkanes, etc.) will degrade more slowly.

Crude oil released into a lake environment will generally spread as a slick or sheen, depending upon the ambient temperature and viscosity of the oil. Light crude oils might spread out to form very thin slicks or sheens, whereas heavy crude oils will form thicker slicks, with associated sheens. Depending upon the volume of crude oil released, the size of the water body, and weather conditions, the oil could spread out to cover the whole surface of the lake. Alternatively, strong winds might herd the released oil to the downwind side of the lake. There, the oil might be driven onto shore, and wave action might entrain some of the released oil into the water column as droplets of various sizes.

When oil comes into contact with sediment, interactions between the oil and the sediment can result in the formation of aggregates that have a density greater than that of water. Two main types of interaction occur: small droplets of oil suspended in the water can become coated with adhering fine sediment particles to form OPAs. Light crude oils with low viscosity are more readily entrained into water as small droplets than heavy crude oils. Therefore, light crude oils may be more prone to formation of OPAs than heavy crude oils. Alternatively, larger droplets, globules, or masses of oil can acquire silt, sand or gravel-sized particles as a result of interactions along shore. The resulting aggregate can also have density greater than that of the water and sink. Diluted bitumens and other heavy oils appear to be more prone to this second type of interaction with sediment particles. Importantly, however, any type of oil can sink as a result of interaction with particles that are denser than water.

The expected effects of released crude oil on water quality are often of short duration (i.e., days rather than weeks or months) because the more water soluble components of crude oil tend to evaporate within the first 24 hours of release. When dissolved in the water column, these compounds also tend to undergo biodegradation quickly (Lee et al. 2015). However, effects on physical habitat (from oil stranded on shorelines or incorporated into sediment) can last for much longer, and potentially for years if not remediated.

Table 7-16 and Table 7-17 provide a summary of the expected environmental effects of oil releases to lakes. Table 7-16 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-17 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-16 Effects of Oil on Lakes by Oil Characteristic

LAND COVER RECEPTOR: Lakes				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Comments**
Density	Light crude oils have API gravity of >31.1°.	Medium crude oils have API gravity of 22.3-31.1°.	Heavy crude oils have API gravity <22.3°, with diluted bitumens generally falling in the range of API gravity between 16 and 23°.	Oils of API gravity >10° will float on fresh water at 15 °C. Therefore, the fresh oils are all expected to float on water.
Viscosity	Light crude oils have viscosity generally in the range of 5 to 50 cP. Low viscosity oils are more likely be become entrained into the water column as small droplets, where mixing energy is high (e.g., windward shorelines).	Medium crude oils have viscosity generally in the range of 100 to 350 cP.	Heavy crude oils have viscosity generally in the range of 350 to 500 cP, although this rises rapidly with weathering. With higher viscosity, heavy crude oils are more resistant to becoming entrained into the water column as small droplets, although larger globules of oil may temporarily become submerged and re-surface.	Viscosity decreases with temperature, and increases with weathering.
Volatility	Contains a large fraction of volatile low molecular weight hydrocarbons; most prone to weathering by volatilization.	Intermediate in volatility and tendency to weather through volatilization between light and heavy crude oil.	The fraction of volatile low molecular weight hydrocarbons depends upon the oil type. Conventional heavy crude oils may have relatively low volatiles content. However, diluted bitumens contain diluent, which may (e.g., condensate) or may not (e.g., synthetic crude oil) contain a large volatile component. CLWB is an example of a diluted bitumen with a relatively large component of condensate and a volatile content similar to that of many light crude oils.	High volatility is generally correlated with low density, and low viscosity in crude oils.
Solubility in Water	Contains a large fraction of soluble low molecular weight	Intermediate in proportions of soluble low molecular weight hydrocarbons	The fraction of soluble low molecular weight hydrocarbons depends upon the oil type. Conventional heavy crude oils	Undiluted bitumen is virtually insoluble, but diluent added to bitumen contains a high

Table 7-16 Effects of Oil on Lakes by Oil Characteristic

LAND COVER RECEPTOR: Lakes				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Comments**
	hydrocarbons, and therefore can release relatively water soluble constituents to lake water, particularly if mixing energy is high and small oil droplets become entrained into the water column.	between light and heavy crude oil.	may have relatively low solubility. However, diluted bitumens (e.g., 2010 Marshall release) contain diluent, which may (e.g., condensate) or may not (e.g., synthetic crude oil) contain a large component of relatively water-soluble aromatic compounds.	fraction of soluble low molecular weight hydrocarbons.
Adhesion	Low adhesion to surfaces, and tending to weather quickly when deposited as a thin layer on exposed surfaces.	Intermediate adhesion to surfaces between light and heavy crude oil.	High adhesion to surfaces, and weathering more slowly due to greater asphaltene content than lighter crude oils.	Oil may adhere to surfaces such as substrates, debris, flora, and fauna. Heavier oils tend to be more adhesive, and to be deposited as a thicker and more persistent layer, than lighter crude oils.
Emulsification	Unlikely to occur (content of asphaltenes in light crude oil is low).	Unlikely to occur (content of asphaltenes in medium crude oil is low).	Asphaltenes are present in heavy crude oils. Conventional heavy crude oils tend to form emulsions readily. However, diluted bitumens appear to have low potential to form emulsions.	Emulsification is less likely to occur in fresh water than in salt water, even for releases of heavier oils, because there generally is not enough mixing energy to create stable emulsions.

Table 7-17 Effects of Oil on Lakes by Environmental Characteristic

LAND COVER RECEPTOR: Lakes				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Wind speed and direction	Low velocity winds may result in limited spreading or containment of oil.	Moderate velocity winds can have some ability to transport oil across lakes or to contain the oil to an area of a lake, depending on the location of the release and direction of the wind.	High velocity winds can transport oil across lakes or contain the oil to an area of a lake, depending on the location of the release and direction of the wind. High winds may also cause entrainment of oil, particularly low-viscosity oil, into the water column.	Heavy fuel oil released in Wabamun Lake in 2005 was spread by strong winds to the north, east and west shores (Anderson 2006).
Wave action	Low wave action may result in little or no dispersion of oil in water.	Moderate wave action can result in some dispersion of oil in water, particularly low-viscosity oils.	High wave action can result in substantial dispersion of oil in water, with low-viscosity oils more susceptible than high viscosity oils.	Dispersion of crude oil as small droplets into the water column can promote dissolution of more water soluble hydrocarbon constituents (promoting acute toxicity to aquatic life). It can also facilitate interactions with suspended mineral particles in the water column, leading to OPA formation and potential sinking of the aggregate.
Ice cover	Without ice cover, crude oil will spread over the water surface as a result of gravity (facilitated by low viscosity and surface tension) or wind action.	Patchy or partial ice cover will have a limited effect on oil movement on the water surface, but low temperatures will limit spreading due to increased viscosity of the oil.	Full ice cover and low temperatures will limit the ability of oil to penetrate into the water column. Snow pack on ice may also absorb and limit the spread of oil, facilitating its recovery. Oil released under the ice, or entering a lake with river flow, may spread under the ice and be difficult to track.	Ice cover will slow the spread of released oil due to the higher and surface tension induced by cold temperatures. Volatility and biodegradation rates are also reduced at low temperatures.

Table 7-17 Effects of Oil on Lakes by Environmental Characteristic

LAND COVER RECEPTOR: Lakes				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Biodegradation	Low rates of biodegradation can result in slower weathering and increased persistence of oil. Biodegradation rates are typically low when oxygen is limiting or absent. Some hydrocarbons, particularly resins and asphaltenes, are resistant to biodegradation. These substances tend to be more abundant in heavy oils than in light oils.	Moderate rates of biodegradation can increase the rate of oil weathering. Aerobic biodegradation can deplete local dissolved oxygen concentrations.	High rates of biodegradation can result in rapid weathering of oil. Aerobic biodegradation can deplete local dissolved oxygen concentrations. Light crude oils generally biodegrade more rapidly and more completely than heavier oils.	Rates of biodegradation depend on composition of the oil, temperature, dissolved oxygen concentration, and nutrient availability (Lee et al. 2015).
Temperature	At low temperatures, oil viscosity, density, and surface tension increase, and volatility of low molecular weight hydrocarbons decreases. Biodegradation rates are also low.	At moderate temperatures, oil viscosity, density, and surface tension decrease and volatility of low molecular weight hydrocarbons increases, leading to greater potential for spreading of oil. Biodegradation rates increase with increasing temperature.	At high temperatures, oil viscosity, density and surface tension are at a reduced, increasing the potential for spreading and dispersion of crude oil. Low molecular weight hydrocarbons are more volatile at high ambient temperature. Biodegradation rates are highest at high temperatures in freshwater. Some hydrocarbons, such as low molecular weight aromatic hydrocarbons, are more soluble at high temperatures (Lee et al. 2015).	Lake temperature is affected primarily by season.
Dissolved	Low oxygen	Most lakes have moderate	High oxygen environments (saturated)	Oxygen is typically not a

Table 7-17 Effects of Oil on Lakes by Environmental Characteristic

LAND COVER RECEPTOR: Lakes				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
oxygen	environments typically occur in deep zones of stratified lakes, in sediment pore water, or in winter under ice cover. Low oxygen availability limits aerobic biodegradation of oil. Anaerobic degradation of oil can occur but rates are slower than for aerobic processes.	oxygen levels (not fully saturated), especially in sub-surface waters. Oxygen levels are typically greatest near the surface due to wave action and diffusion of oxygen into the water. The rate of phytoplankton growth and degradation influences oxygen levels in the water column. Microbial degradation of crude oil could deplete the oxygen concentration in lake water.	typically occur in near-surface water, or during spring and fall overturn in dimictic lakes. The presence of phytoplankton can result in super-saturation of oxygen in daylight hours, with low oxygen concentrations occurring at night due to dark respiration.	limiting factor to biodegradation except in deep or strongly stratified aquatic environments, and there, only in the unlikely event that oil sinks into the anaerobic environment (Lee et al. 2015). However, almost any sediment can have limiting oxygen conditions, and oil in sediments can be expected to degrade slowly.
Nutrient supply	Oligotrophic lakes contain naturally low levels of nitrogen, phosphorus, and organic carbon. Low nutrient availability can limit the capacity for biodegradation (Lee et al. 2015).	Mesotrophic lakes contain moderate levels of nitrogen, phosphorus, and organic carbon that can support oil biodegradation in a lake (Lee et al. 2015).	Eutrophic lakes provide elevated levels of nitrogen, phosphorus, and organic carbon (either naturally or through human activities), which can support a high capacity for oil biodegradation in a lake (Lee et al. 2015).	Nutrient availability varies seasonally and from lake to lake. Nutrient levels are typically highest in spring and fall, at the time of overturn. Nutrients are sometimes added to oiled environments in order to stimulate microbial degradation of oil (Lee et al. 2015).

Table 7-17 Effects of Oil on Lakes by Environmental Characteristic

LAND COVER RECEPTOR: Lakes				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Suspended Solids	Low levels of suspended solids, typical in open water areas of lakes, provide a low potential for oil to interact with particles and form aggregates.	Moderate levels of suspended solids may occur in near shore areas of lakes, where sediments can be suspended from the bottom, transported from shore by overland flows, or introduced at stream inflows (e.g., during spring freshet and rain events). There is some potential for oil to interact with particles and form aggregates. These aggregates may be neutrally buoyant and enter the water column or become denser than water and sink to the bottom (Lee et al. 2015).	High concentrations of suspended solids may occur in near shore areas of lakes, where sediments can be suspended from the bottom, transported from shore by overland flows, or at stream inflows (e.g., during spring freshet and rain events). There is high potential for oil to interact with particles and form aggregates. These aggregates may be neutrally buoyant and enter the water column becoming denser than water and sink to the bottom (Lee et al. 2015).	Formation of OPAs is limited in fresh waters (i.e., at low levels of salinity). In addition, high levels of both turbulent mixing energy and suspended sediment are required in order for oil-particle interaction to be an important process in the fate of released crude oil. Hospital et al. (2016) concluded that these conditions are rarely met in the lower Fraser River and Salish Sea, and therefore they are also unlikely to be present in most inland lakes.

7.1.2.4 Rivers

7.1.2.4.1 Description

Rivers and streams can be defined as permanent flowing fresh-water bodies surrounded by land, and distinguished loosely on the basis of size (width, depth, flow volumes) and location or stream order within a watershed. They can be differentiated from permanent standing waterbodies such as lakes and ponds on the basis of whether flow is dominated by hydraulic factors (i.e., flow as in rivers and streams) or other factors such as wind or thermal circulation (i.e., water circulation as in lakes). Rivers are included in the present effects assessment of land cover receptors due to their prominence in the proposed ROW routes, their importance to aquatic and terrestrial life, and the role that they can play in transporting released crude oil away from an accidental release point. Rivers provide habitat for fish, amphibians, plants, benthic invertebrates, insects, birds, and mammals, and provide valued recreational, aesthetic, cultural, and economic values for humans.

The effects assessment for rivers focuses on observed and expected physical and chemical effects of released oil on rivers and streams. Effects of accidental crude oil releases on aquatic biota (e.g., benthic invertebrates, fish, and aquatic plants) are discussed separately. Crude oil released in rivers generally floats, interacting with shorelines as it moves downstream. Depending upon the crude oil type, a considerable amount of the released oil may escape to the atmosphere as VOCs. However, crude oil can also enter the water column as the dissolved water-soluble fraction of oil, dispersed as fine droplets, or mixed with soil or sediment as OPAs. Depending upon its interactions with suspended sediments and shoreline, crude oil may also be deposited to bed sediments in depositional areas (such effects are discussed elsewhere).

7.1.2.4.2 Observed Effects

There is potential for oil released accidentally from a pipeline to reach a stream or river, either at a pipeline crossing location, or after overland flow away from the pipeline right of way. In either case, released crude oil that reaches a watercourse can be transported downstream with the flowing water. To better understand the potential effects of oil releases on riverine resources, observed effects are compiled from four case studies where oil was accidentally released into river environments.

> ***Asher Creek, Missouri (1979)****: In August 1979, a pipeline burst, releasing approximately 9,500 barrels of unspecified domestic crude oil into Asher Creek, in southwest Missouri, during low flow conditions (Crunkilton and Duchrow 1990). A responsible party has not been identified for this incident. The creek originates in springs upstream from the release location. Information about hydrocarbon concentrations in water was not provided, but dissolved oxygen, pH, and conductivity levels in water were not changed by the release. The first site downstream from the release point was described as being "completely inundated with oil". Additional study sites were located downstream of six surface skimming siphon dams which were placed across the stream to retain floating oil*

after the release occurred (Crunkilton and Duchrow 1990). These dams were reported to contain most of the released oil. However, upstream of the dams, oil penetrated riffle substrates and coated the stream bed. Oil that entered riffle substrates due to mixing was visible for over a year (Crunkilton and Duchrow 1990). Low water volumes in these headwaters, particularly during summer at the time of the release, provided limited dilution of the oil. The first scouring floods occurred in February, six months after the release, and helped to dissipate the oil. Oil was observed as a sheen on the water surface after disturbing the substrate up to 453 days after the release at Site 2 (above the siphon dams), and up to 336 days after the release at Site 3 (below the siphon dams), but no oil was observed at other sites during the 532 day study (Crunkilton and Duchrow 1990).

***Pine River, British Columbia**: On August 1, 2000, a pipeline owned by Pembina Pipeline Corporation ruptured and released approximately 6,200 barrels of sour light crude oil, of which approximately 2,800 barrels entered the Pine River in British Columbia (BC MOE 2000a). The Pine River is fast flowing, and oil was dispersed up to 50 miles downstream. The fast flowing water allowed rapid dispersion of acutely toxic fractions of the oil into the river water. Oil was stranded and settled in depositional areas along the banks, in back eddies, and in other slow-flowing areas, as well as on organic debris and logjams (AMEC 2001 in Lee et al. 2015). Heavy rainfall later in August and September mobilized stranded oil and oil-contaminated debris and sediments; high water levels scoured some of the more heavily oiled depositional areas. Oil was recovered from the river over a period of two months, with about 91% of the released oil recovered (Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015). Most of the oil that remained unaccounted for was considered likely to be located in river sediments, or trapped in woody debris dams in the river. Some of the emergency response activities (e.g., removal of log jams and woody debris, altering of back channels, bank armoring, and presence of heavy machinery in the river) also resulted in habitat damage (Summers 2004 in Bustard and Miles 2011).*

The Pine River is an important source of drinking water for the town of Chetwynd, British Columbia, and as a result of the release, the town closed its water intake and used alternate water sources. Effects on water quality included visual and olfactory evidence of oil contaminants over a 50-mile section of river. After three weeks, hydrocarbons were still detectable chemically in water but had decreased rapidly to below British Columbia water quality guidelines due to evaporation, degradation, and natural dispersion (Lee et al. 2015). Sheen was largely restricted to back eddies and other calm areas along shorelines. The rapid decline in hydrocarbon concentrations in river water was attributed to the characteristics of the light crude oil released (rapid evaporation, dissolution, degradation, and natural dispersion).

***Marshall, Michigan**: On June 25 and 26, 2010, the Line 6B pipeline owned by Enbridge ruptured and released approximately 20,000 barrels of heavy crude oil, of which approximately 8,000 barrels entered Talmadge Creek, a tributary to the Kalamazoo River, near Marshall, Michigan (NTSB 2012a, Enbridge 2013a). The released oil was a combination of Western Canadian Select (23%) and CLB diluted bitumen (77%) (Enbridge 2013a). The release occurred on the floodplain of Talmadge Creek, where wetlands are abundant (USFWS et al. 2015a). The Kalamazoo River is a meandering, low-gradient river with diverse channel and floodplain features, extensive floodplain forests and wetlands, off-channel water bodies, and impoundments (Dollhopf et al. 2014). Oil was transported downstream in the Kalamazoo River, which was in flood at the time of the release, to Morrow Lake (an impoundment in the river 36.5 miles downstream). Oil was deposited on river shoreline, riparian, and depositional areas and along the shores at the delta of Morrow Lake (USFWS et al. 2015a), affecting approximately 40 miles of river (80 miles of shoreline and adjacent lands) (Dollhopf and Durno 2011). There was subsequent associated disturbance from oil removal efforts (removal of riparian vegetation and sediment, access road construction; Dollhopf and Durno 2011). Channel margins, backwaters, side channels, oxbows, and impoundments provided depositional areas for the oil.*

Major factors affecting OPA formation include the quantity and viscosity of the oil, oil-water interfacial tension, and chemical composition of the oil; the quantity and type suspended sediment particles; the magnitude and variability in physical energy of the aquatic environment; temperature and salinity (Fitzpatrick et al. 2015). The first step to forming OPAs lies with the initial breakup of a slick of oil into oil droplets. Once spilled into a water body with turbulence created by waves or currents, floating oil can break up into droplets. In the absence of a surfactant, smaller droplets are generated the viscosity of the oil are low. Oil viscosity can vary by orders of magnitude among different types of oil, and at different temperatures. The viscosity of a heavy crude oil or bitumen is at least 1,000 times that of light crude such as a product from the Alaska North Slope or Bakken Formation (Fitzpatrick et al. 2015). The size of the oil droplet is a very important factor in the transport and fate of the oil and its interaction with particles. Because large droplets have higher buoyancy than smaller droplets, they tend to float to the water surface, whereas smaller droplets could be driven more easily in the water column as a result of mixing energy (Fitzpatrick et al. 2015). Small droplets would only need to interact with a few, small suspended sediment particles in order to achieve neutral or negative buoyancy relative to water. Larger droplets would require considerably more interaction with suspended sediments to reach a sinking density, or could potentially split into "floating" and "sinking" portions. Particle size, amount, and type are important to the formation of OPAs. Clay-sized mineral particles are effective at forming OPAs. However, most natural waters have a range of particle sizes, which may vary with the

amount of mixing resulting from waves or currents. Particles may be smaller than the oil droplet and form a coating, or they may similar in size to the aggregate (Fitzpatrick et al. 2015). However, the practical implication of the foregoing discussion is that classical OPA formation may be insufficient to explain the behavior of crude oil that was released to the Kalamazoo River. Zhou et al. (2015) reported the results of wave tank tests that showed conventional light crude oil forming small droplets that interacted with natural river sediments at realistic concentrations to form OPAs and sink, whereas a more viscous diluted bitumen remained floating on the surface of the tank, without forming entrained droplets, and without interacting with suspended sediments or sinking.

Some features of the Kalamazoo River likely enhanced the formation, re-suspension, and deposition of OPAs. The Enbridge Line 6B pipeline release happened during a flood on the Kalamazoo River. On the basis of later measurements of suspended sediment it was inferred that the river had relatively low suspended sediment concentrations at the time of the spill (less than 100 mg/L; Fitzpatrick et al. 2015) with suspended particle sizes mainly in the silt-sized range. Water temperatures were warm. Floodwater increased turbulence in river flows, and mixing from flows over two dams may also have played a role, although OPAs and submerged oil accumulated in the first 3 miles (5 km) of river length, between the spill source and the first dam (Fitzpatrick et al. 2015). However, the importance of oil welling upwards through overburden materials from the buried pipeline to the surface, and subsequent overland flow between the failure location and Talmadge Creek has not been widely discussed. The accumulation of soil particles by liquid heavy fuel oil was considered to be an important process in the sinking behavior of that oil following the Wabamun Lake oil spill (Hollebone et al. 2011). It is possible that interactions between bulk diluted bitumen and soil particles up to sand grain size may account for some of the observed deposition of diluted bitumen to sediments in the Kalamazoo River.

Surface water samples were collected between July 2010 and April 2012 from the Kalamazoo River and Morrow Lake (MI DCH 2014b). Parent and alkylated PAHs were analyzed at various depths within the water column (USFWS et al. 2015a). Surface water analyses were conducted to evaluate potential effects on human health and on exposure of fish embryos to oil constituents. The July and August 2010 laboratory results showed that most chemical constituents were below water criteria for both the USEPA and the MI DEQ. The regulatory agencies agreed additional sampling was unnecessary.

***Red Deer River, Alberta**: On June 7, 2012, about 1.9 miles north of Sundre, Alberta, floodwaters 10 times higher than typical June flows eroded the stream bed and banks, exposing the Plains Midstream Canada ULC pipeline, which then ruptured (Alberta Energy Regulator 2014). Approximately 2,900 barrels of light crude oil*

were released into Jackson Creek, a tributary of the Red Deer River. Oil travelled at least 25 miles downstream to Gleniffer Lake reservoir, where booms contained the floating oil. Dissolved hydrocarbons were detected in river water up to 5 miles farther downstream (Alberta ESRD 2012a). Because of the high water levels at the time of the release, the majority of oil stranded in backwater areas, under trees and debris, and in highly braided river margins, and also mixed with silt and sediments well above the normal high water mark for the river (Teichreb 2014).

The main concerns were for drinking water quality, but monitoring indicated only low levels of hydrocarbons (below Health Canada guidelines for drinking water quality) at intakes along the river downstream of the Gleniffer Lake reservoir (Alberta ESRD 2012a, b). No studies were found of effects on habitat in the river. It is likely that concerns about habitat were reduced because of the small volume of released oil in proportion to the large volume of river water at flood stage (large dilution), and the type of oil released (light crude oil, which weathers quickly) (Alberta ESRD 2012a).

7.1.2.4.3 Expected Effects of Released Oils

The main effects of oil released into a watercourse are changes in water quality and changes in physical habitat. Effects vary, depending on characteristics and volume of the released oil, duration of release (instantaneous versus protracted duration), and environmental conditions within the receiving waters (current velocity, volume of river/stream channel, morphology of channel—i.e., straight versus serpentine, presence of backwaters, oxbows). Relevant oil characteristics that will directly affect the fate and effects of released oil include (but are not limited to) density, viscosity, volatility, solubility, surface tension, adhesion, and emulsification, which affect behavior of oil on water and the weathering of oil.

A release of diluted bitumen is expected to result in environmental effects similar to those observed for other heavy crude oils. Diluted bitumen does not separate into diluent and bitumen components when released (Taylor et al. 2014; Zhou et al. 2015; Fingas 2015a). Diluted bitumen floats on water and can be stranded on shorelines. If the oil first travels over land, it can pick up soil and organic matter and form OPAs in water, which can sink. OPA can form in water as well, the degree of OPA formation depending on concentrations of suspended particulates in the water column and the amount of water column turbulence. Some of the diluent (e.g., condensate) present in diluted bitumen may evaporate quickly, but diluents also contain a wide range of individual hydrocarbon compounds, and the rapid initial weathering phase of diluted bitumen samples is typically followed by a slower secondary phase.

The effects of released oil on water quality are often transient (days) because the acutely toxic components (low molecular weight hydrocarbons like BTEX, some PAHs, and some alkanes) tend to weather (evaporate) quickly, or when dissolved in the water column, degrade quickly. Higher molecular weight PAHs are less likely to be acutely toxic to aquatic life but break down slowly (over months or years), so they persist and can result in chronic effects on aquatic biota. Effects

on physical habitat (from oil stranded on shorelines and sediment) can result in habitat smothering and may last for much longer, especially where appropriate remedial actions are not taken. Soluble constituents in the deposited oil can dissolve into the water column over time resulting in ongoing toxicity to aquatic organisms. Effects of hydrocarbon contaminants on river sediments are discussed elsewhere.

Environmental characteristics affecting the behavior and fate of crude oil in watercourses include water flow, channel geometry, hyporheic flow (i.e., beneath and alongside a stream bed where there is mixing of surface waters and shallow groundwater), biodegradation, temperature, dissolved oxygen, nutrient supply, suspended sediment, and sunlight exposure. In rivers and streams, oil is predominantly transported by surface currents. River flow volume and velocity are determined by watershed size, runoff and other water inputs, river slope, and channel characteristics. Physical characteristics may range from small headwater streams with little dilution potential and boulder substrates with little depositional habitat, to higher order streams and rivers with broad floodplains, complex channel morphology and habitat, and abundant depositional areas. Water channels can be simple (e.g., artificially channelized areas) or complex, with meanders, braided areas, backwaters, shoals, and structures such as bridge supports, dams, and jetties, which will result in complex patterns of oil transport and deposition. The oil initially moves on the surface with the current. Evaporation and other weathering processes remove low molecular weight hydrocarbon fractions. Water turbulence can disperse oils that have low viscosity as fine droplets in the water column, where soluble fractions can dissolve in the water. In areas of lower turbulence (slower flows), oil droplets can coalesce and float to the surface again.

Oil can become stranded on shoreline areas, shoals, and shallow, slow-flowing areas when water levels recede. Stranded oil can be re-mobilized and flushed downstream when flows and water levels later increase. If there is a naturally high sediment load in the river (e.g., during a freshet), or if oil travels over land and picks up soil particles, OPAs can form, leading to oil deposition to sediment in slow-flowing areas.

Seasonal weather conditions also have an effect. Releases that occur during the spring freshet or high rainfall events will be rapidly transported downstream. High water levels could result in oil being deposited to riparian habitat, becoming stranded as water levels drop. Releases into ice-covered rivers during winter may be isolated initially, but travel downstream under the ice such that locating and recovering the released oil is challenging. Any residual oil that is not recovered, or oil that has been sequestered beneath the ice, may be remobilized when the ice melts and flow increases.

The effects of crude oil releases on surface water quality typically last only a short time after the release. Crude oil typically undergoes rapid initial mass loss due to weathering. Stranding along shorelines also results in removal of released oil from the water surface. Most hydrocarbons are only sparingly soluble to insoluble in water, so effects on water quality are generally short lived. Remedial activities may help speed up recovery of a water body through collection of oil.

Effects on river from oil stranded on shorelines or deposited to sediment can last for much longer, and long-term or persistent contamination of these physical habitat components can result in chronic low-level release of potentially toxic constituents of the crude oil (e.g., PAHs) back to the water column.

Table 7-18 and Table 7-19 provide a summary of the expected environmental effects of oil releases to rivers. Table 7-18 considers the effects of specific oil characteristics or oil type on the expected type and scope of environmental effects. Table 7-19 considers the effects of environmental factors on the expected types and scope of environmental effects.

Table 7-18 Effects of Crude Oil on Rivers by Oil Characteristic

LAND COVER RECEPTOR: Rivers				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Comments**
Density	Low density oils, float on water.	Intermediate in density between light and heavy oils; will float on water.	High density oils; pipeline tariffs require density to be less than 0.94. Fresh diluted bitumen will float on water.	The density of crude oil or diluted bitumen increases with evaporation of lighter components.
Viscosity	Low viscosity oils, have a high tendency to spread and disperse, both on the surface of the water, and potentially as fine droplets in the water column where mixing energy is sufficient.	Intermediate in viscosity, spreading and dispersal characteristics between light and heavy oils.	Heavy crude oils tend to be viscous. Fresh diluted bitumens have viscosity that is regulated through the addition of a diluent.	Viscosity of crude oil decreases with rising temperature, and increases as a function of weathering after release. Diluted bitumens may undergo more rapid initial weathering than conventional crude oils if the diluent is volatile (e.g., condensate). Diluted bitumens contain more diluent in winter than in summer in order to compensate for temperature effects.
Volatility	Light crude oils typically contain a large fraction of volatile (low molecular weight) hydrocarbons. These are prone to weathering by volatilization and dissolution.	Intermediate in volatility and tendency to weather through volatilization between light and heavy oils.	The fraction of volatile low molecular weight hydrocarbons depends on the oil type. Conventional heavy crude oils may have relatively low volatile content. However, diluted bitumens contain diluent, which may (e.g., condensate) or may not (e.g., synthetic crude oil) contain a large volatile component. CLWB is an example of diluted bitumen with a relatively large component of condensate and a volatile content similar to that of many light crude oils.	Evaporation of volatile components increases with temperature. As volatilization occurs, the density of the residual oil will increase. Diluted bitumen may undergo a rapid initial loss of volatiles, followed by a secondary phase of slow weathering. In contrast, light and medium conventional crude oils that contain more mid-range hydrocarbon compounds have a more gradual weathering behavior.

Table 7-18 Effects of Crude Oil on Rivers by Oil Characteristic

LAND COVER RECEPTOR: Rivers				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Comments**
Solubility	Light crude oils typically contain a large fraction of relatively water soluble (low molecular weight) hydrocarbons.	Intermediate in proportions of soluble low molecular weight hydrocarbons between light and heavy oils.	The fraction of relatively water soluble low molecular weight hydrocarbons depends on the oil type. Conventional heavy crude oils may have relatively low solubility. However, diluted bitumens contain diluent which may (e.g., condensate) or may not (e.g., synthetic crude oil) contain a large component of relatively water-soluble compounds. CLWB is an example of diluted bitumen with a relatively large component of condensate, with BTEX content similar to that of many light crude oils.	Undiluted bitumen has a very low water soluble fraction, but diluent added to bitumen contains a high fraction of soluble LMW hydrocarbons. Dissolution of the lighter fraction can increase oil density.
Adhesion	Relatively low adhesion to surfaces.	Intermediate adhesion to surfaces between light and heavy crude oil.	High adhesion to surfaces.	Oil may adhere to surfaces such as substrates, debris, flora, and fauna.
Emulsification	Unlikely to occur (content of asphaltenes in light crude oil is low).	May occur, depending upon crude oil chemistry.	Asphaltenes are present in conventional heavy crude oils, and these can have a high potential to emulsify. However, diluted bitumens, which contain very large amounts of asphaltenes, appear to have low potential to form emulsions.	Emulsification is less likely to occur in fresh water than marine, even for releases of heavier oils, because there is often not enough consistent and protracted mixing energy to create stable emulsions.

Table 7-19 Effects of Crude Oil on Rivers by Environmental Characteristic

LAND COVER RECEPTOR: Rivers				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Water Flow	Rivers in low flow condition can have exposed substrate (e.g., sandbars) or debris upon which released oil can adhere. Oil will be transported downstream at a low speed, with little dilution. Turbulence levels in the stream are also typically at low levels. Floating oil will likely remain floating, but OPAs can sink to the bottom in slow moving water.	Rivers in moderate flow conditions typically have downstream transport velocities and turbulence levels that are intermediate between low and high flow condition. In-stream features such as sandbars will typically be submerged, but the river remains within its normal banks.	Rivers in high flow conditions typically have the highest downstream transport velocities and turbulence levels within the main river channel. At high flow, the river level may exceed that of the normal banks, with flow extending laterally into riparian or floodplain areas. In these areas, there may be areas of low flow and high potential to trap floating and submerged crude oil.	High river flow conditions can result in the entrainment and virtual "disappearance" of light crude oils as they are dispersed over a large area. On the other hand, the Kalamazoo River oil spill resulted in extensive oiling of floodplain areas, as well as submergence and sinking of the heavy crude oil with subsequent accumulation in areas of quiet water such as the Morrow Lake impoundment.
Turbulence	Crude oil is likely to remain floating on the surface of rivers that have low turbulence levels, regardless of the viscosity of the oil.	Under moderately turbulent flow conditions, light crude oils may become entrained into the water as small droplets, which may then interact with suspended sediment (leading to sinking behavior). Entrainment of oil as small droplets will also promote dissolution of relatively water soluble fractions of the crude oil.	Under highly turbulent flow conditions, both light and heavy crude oils may become entrained into the water. However, the droplet size profile of heavy crude oils will tend to remain skewed towards larger droplet sizes, due to its higher viscosity and surface tension.	Turbulence can be induced in river flows as a result of slope, irregular substrate type, overall water flow, and in-stream features such as natural waterfalls or man-made weirs and dams.

Table 7-19 Effects of Crude Oil on Rivers by Environmental Characteristic

LAND COVER RECEPTOR: Rivers				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Suspended Sediment	Low concentrations of suspended sediment and turbidity typically occur in clear, small streams; in slow moving depositional areas; during low flow periods; or in streams where water inputs are dominated by groundwater. Any of these waterbodies can also experience high sediment loads during freshet flows. There is low potential for oil to interact with particles to form aggregates.	Moderate concentrations of suspended sediment and turbidity typically occur in mid-sized streams; during moderate flow periods; and in streams where inputs include some overland flow. There is some potential for oil to interact with particles and form aggregates. The aggregates may be neutrally buoyant and enter the water column, or sink.	High concentrations of suspended sediment and turbidity typically occur in low gradient rivers and large streams; in fast moving active erosional areas; in streams where there is substantial input from overland flow; and during times of high flow (e.g., spring freshet or high rainfall events). There is high potential for oil to interact with particles and form aggregates that may be neutrally buoyant or sink (Lee et al. 2015).	Geological characteristics, soil types, and land use in the surrounding watershed play large roles in determining the baseline and maximum suspended sediment concentrations in streams and rivers. The baseline may be low (i.e., clear-flowing water), moderate or high (i.e., water that is routinely muddy in appearance), but regardless of the baseline levels, suspended sediment concentrations typically peak during spring freshet and in response to high rainfall events.
Temperature	At low environmental temperatures, oil density, viscosity and surface tension are higher, and volatility of low molecular weight hydrocarbons is lower. Biodegradation rates are also limited.	At moderate temperatures, properties of density, viscosity, surface tension, volatility and biodegradation are at intermediate values.	At high environmental temperatures, oil density, viscosity and surface tension are lower, and volatility of low molecular weight hydrocarbons is higher. Biodegradation rates also tend to be higher, provided oxygen and nutrient availability are not limiting.	River temperature is affected by seasonal changes in ambient temperature, by the temperature and amount of inflowing groundwater, tributary streams and overland flow. Unshaded streams and rivers are more exposed to daily temperature fluctuations than shaded watercourses.

Table 7-19 Effects of Crude Oil on Rivers by Environmental Characteristic

LAND COVER RECEPTOR: Rivers				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Ice Cover	In winter, the ground may be snow covered, but rivers may remain open. Without ice cover, the behavior of crude oil in rivers is generally similar to its behavior in other seasons.	Moderate ice cover and low temperatures may limit the spread of crude oil in rivers, but will also pose challenges to oil spill response and recovery operations.	When there is high ice cover on a river, released oil may pool on the surface of the ice, providing an opportunity to recover the oil or limit its spread. If crude oil is released into a river below the ice, it can move under the ice surface, accumulating in hollows under the ice, and in areas of low water flow near the river margins.	Ice cover implies cold temperatures and low river flow rates, which will slow the spread of released oil due to effects on viscosity. Crude oil released beneath ice cover has limited exposure to the atmosphere, and this will force more of the low molecular weight hydrocarbon to dissolve in water than would otherwise be the case. In combination with low river flow rates, this may result in higher potential for toxicity to fish. Ice cover may impede recovery operations, leading to a secondary episode of crude oil movement in the watercourse during the spring melt period.

Table 7-19 Effects of Crude Oil on Rivers by Environmental Characteristic

LAND COVER RECEPTOR: Rivers				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Dissolved oxygen	Low oxygen environments (e.g., <5 mg/L) may occur in deep, slow moving depositional areas of rivers, or in underlying sediment pore water. Low oxygen availability limits biological communities, as well as limiting aerobic biodegradation of oil. Anaerobic degradation of oil can occur, but rates are much slower than for aerobic processes.	Many rivers are typically under-saturated with dissolved oxygen, particularly during warm periods. However, oxygen concentrations are usually adequate to support a wide variety of aquatic life, and would not be limiting to biodegradation of crude oil.	High oxygen environments (saturated to super-saturated) occur in higher gradient streams where water turbulence results in greater entrainment of oxygen. Super-saturation can also occur as a result of photosynthetic activity in streams and rivers, particularly during daylight hours in the summer. High oxygen environments can facilitate higher rates of aerobic biodegradation.	Oxygen is typically not usually a limiting factor to biodegradation of crude oil in rivers, except in deep, slow moving areas or in sediment pore-water. Biological communities are typically adapted to the prevailing oxygen regime, although still susceptible to events that deplete oxygen.
Nutrient supply (nitrogen, phosphorus, organic carbon)	Nutrient supply can be low in small streams, and can limit the capacity for microbial biodegradation of hydrocarbon residues.	Moderate nutrient availability is typical of mid-sized streams.	High nutrient availability often occurs in rivers and larger streams (as a result of both natural and anthropogenic inputs), and may support a higher capacity for microbial degradation of hydrocarbon residues.	The river continuum concept (Vanotte et al. 1980) proposes that rivers are in a constant but predictable state of development, from headwater reaches to their mouths. This has implications for biological communities, as well as abiotic factors such as nutrient supply. Nutrient levels in rivers also vary as a result of surrounding land use (sources of nutrients) and season.

Table 7-19 Effects of Crude Oil on Rivers by Environmental Characteristic

LAND COVER RECEPTOR: Rivers				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Sunlight exposure	The light environment of rivers varies in relation to a range of factors including the degree of shading (greatest in small watercourses that are overhung by trees), as well as internal factors such as the levels of suspended sediment and dissolved organic carbon in the water.	N/A	Larger watercourses may be partially shaded along their banks, but are unshaded at mid-stream. However, larger watercourses are also more likely to have higher levels of suspended sediment in the water, which may limit light transmission through the water column.	Photo-oxidation is a natural remediation process that helps to break down hydrocarbon residues into less persistent and generally less toxic compounds.
Hyporheic Flow	Stream and river beds dominated by fine-grained materials (silts and clays) have low levels of permeability to flow, and will resist entry of crude oil into the hyporheic zone.	Stream and river beds dominated by sand or sand and gravel will potentially admit hyporheic flow, but may also act as a filter bed, limiting entry of crude oil constituents to soluble components that are readily degraded by microbial processes.	Stream and river beds dominated by gravel, cobbles and boulders will readily admit hyporheic flow, and crude oil droplets may also be entrained into the hyporheic environment.	Oil entering the hyporheic zone can become trapped in the sediment by adsorption to particles and can contaminate interstitial sediment pore water. This can have implications for biota ranging from benthic invertebrates to developing fish eggs and embryos that become exposed to residual or persistent crude oil residues.

7.1.2.5 Sediment

7.1.2.5.1 Description

Sediment is defined as the weathered minerals and organic detritus that form bottom substrates in aquatic environments. Suspended sediment is not discussed here; it is included as a water quality parameter in the effects assessment for lakes and rivers. Sediment can be a repository for contaminants, including petroleum hydrocarbons. Therefore, it is included in the effects assessment of land cover receptors due to its importance to aquatic life (fish, amphibians, plants, invertebrates), birds, and mammals that depend upon it.

The dominant substrate type usually reflects the hydrological regime. The largest materials (cobbles and boulders) are typically moved only by extreme high flow events. As a result, the stable substrate in erosional environments is typically composed of cobble, boulder, and gravel which, due to their large size, have substantial pore spaces between them.

In erosional environments (moderate to high flow river systems), sediments are transported by water movement. Fine sediments (generally composed of silt, clay, fine sand and smaller organic detritus) can be suspended in the water column, while coarse sediments (coarse sand, gravel, cobble, boulder and bedrock) remain on the bottom. In depositional environments (lakes, slow flowing or deep sections of streams and rivers), fine sediments drop out of suspension and form deposits on the bottom. Substrate in depositional environments is composed primarily of fine sediments and organic matter, with small pore spaces between particles. In rivers, deposition and erosional processes can occur alternately according to flow conditions. In lakes, depositional processes are dominant, although erosional processes may prevail along exposed shorelines.

The effects assessment for sediment focuses on physical and chemical effects of released oil on sediment quality in lakes and watercourses, and excludes direct effects of oil on aquatic biota (benthic invertebrates, fish, and aquatic plants), which are discussed elsewhere. Oil released in lakes and watercourses typically remains floating on the surface, but can become stranded on the shoreline and sediment as a result of currents and wind-driven movement, or can sink when OPAs form. The oily sediment may accumulate in depositional (low flow or quiet) areas.

In water, the low molecular weight fractions of oil weather quickly, leaving behind more persistent higher molecular weight hydrocarbons, including PAHs and weathered products (e.g., tar balls, OPAs). Deposited oil can be remobilized during times of high flow or high turbulence, resulting in additional exposure of aquatic biota to the contaminants.

7.1.2.5.2 Observed Effects

There is potential for oil released accidentally from a pipeline to reach one of the many lakes and watercourses in Minnesota, where some of the oil may end up on or in the sediments. Observed effects of released oil on sediment are compiled from four case studies described below, where oil was observed to interact with freshwater sediment. These include the 2010

Marshall, Michigan release, 2005 Wabamun Lake, Alberta release, 2000 Pine River, British Columbia release, and 1979 Asher Creek, Missouri release. The case studies described below are for a variety of river and lake receptors, and oil types. Potential effects of differences in the receiving environment and oil type on the behavior and weathering patterns of released oil, and on resulting potential environmental effects are discussed.

> ***Marshall, Michigan**: On June 25 and 26, 2010 a rupture in Enbridge's Line 6B pipeline released approximately 20,000 barrels of heavy crude oil, of which approximately 8,000 barrels entered Talmadge Creek, a tributary to the Kalamazoo River, near Marshall, Michigan (NTSB 2012a, Enbridge 2013b). The released oil was a combination of Western Canadian Select (23%) and CLB diluted bitumen (77%) (Enbridge 2013a). The release occurred on the floodplain of Talmadge Creek, where wetlands are present (USFWS et al. 2015a). The Kalamazoo River is a meandering, low gradient river with diverse channel and floodplain features, extensive floodplain forests and wetlands, off-channel water bodies, and impoundments (Dollhopf et al. 2014). Oil was transported downstream in the Kalamazoo River, which was in flood state at the time of the release, to Morrow Lake (an impoundment in the river 36.5 miles downstream).*
>
> *Oil was deposited on river shoreline, riparian, and depositional areas (backwaters, side channels, oxbows) and along the shores at the delta of Morrow Lake (USFWS et al. 2015a), affecting approximately 40 miles of river (80 miles of shoreline and adjacent lands) (Dollhopf and Durno 2011). There was associated disturbance from oil removal efforts such as the removal of riparian vegetation and sediment and access road construction (Dollhopf and Durno 2011). Some of the oil mixed with soil and organic matter while moving overland and, after entering the river, with suspended sediment in the water column, resulting in the formation of OPAs that submerged in some locations, especially in depositional areas. These aggregates periodically released oil globules and sheen as late as 2014 (Fitzpatrick et al. 2015). Formation of OPAs was likely promoted by the flood conditions. Based on measurements of suspended sediment at the Marshall stream gage after the release, it can be inferred that the river had relatively low suspended sediment concentrations at the time of the release, but that the floodwaters likely increased the turbulence and the presence of suspended particulate matter (Fitzpatrick et al. 2015). In addition, the high organic matter content of sediments (20% or more) resulting from the extensive floodplain wetlands along the Kalamazoo River could have contributed to OPA formation (Fitzpatrick et al. 2015). Some of the submerged oil settled in areas that became anaerobic, which would reduce the rate of biodegradation.*
>
> *About 90% of the oil entering the river was recovered in the first year. This included floating oil, stranded oil in the floodplains of Talmadge Creek and the Kalamazoo River, and submerged oil (Fitzpatrick et al. 2015). The oil weathered,*

increasing the density of the weathered diluted bitumen. In 2011, additional activities to dislodge and disperse submerged oil resulted in a small amount of additional recovery. Submerged OPAs continued to release oil from sediments in the Kalamazoo River and impoundment areas during 2011 to 2014, with surface sheens observed in impounded sections of the river (Fitzpatrick et al. 2015).

Sediment chemistry was studied in 2011, 2012, and 2013 in depositional areas of the river and in Morrow Lake (Enbridge 2014). Levels of PAHs and other oil related compounds were compared to MI DEQ sediment quality values, including threshold effect concentrations (TEC) and probable effect concentrations (PEC) adopted from USEPA standards (MacDonald et al. 2000; USEPA 2003). Numerous samples from the affected areas and also from upstream and reference areas had concentrations of individual and total parent PAHs higher than the TECs; a few samples from the affected area had concentrations higher than the PECs (Enbridge 2014). Concentrations and exceedances of screening levels decreased between 2012 and 2013 (Enbridge 2014).

Sediment toxicity was tested at the same locations as sediment chemistry during 2012 and 2013, using standard laboratory tests with the amphipod (Hyalella azteca) and larval midge (Chironomus tentans). The extent and number of samples showing toxicity decreased from 2012 to 2013 and indicated overall that toxicity was absent from most parts of the river studied (Enbridge 2014). In both years, many samples showed no toxicity, and some samples showed low levels of both toxicity (e.g., 91% survival in Hyalella and 82% survival for Chironomus) and reduced growth. Effects were similar in affected and reference areas of the river, suggesting that the effects on toxicity and growth were associated with factors other than the oil release (Enbridge 2014). Many samples from affected areas of the Kalamazoo River (i.e., the Morrow Lake headpond) contained naturally high levels of total organic carbon, which were expected to reduce bioavailability of the PAHs, many of which bind to organic carbon.

The 2013 study was a sediment quality triad study of depositional areas, bringing together information about contaminant concentrations in sediment, sediment toxicity, and benthic invertebrate communities. Using a weight-of-evidence approach with multiple lines of evidence to evaluate the ecological significance of the residual hydrocarbons in sediment, it was concluded that by 2013, spill-related hydrocarbons in sediment of the Kalamazoo River were not having adverse effects on the aquatic ecosystem (Enbridge 2014). Other findings were that one line of evidence taken alone (e.g., sediment chemistry compared to guidelines) was not enough to identify the effects on the environment, and that many factors other than, or in addition to, the oil release were affecting the aquatic environment.

***Wabamun Lake, Alberta**: On August 3, 2005, a derailed train released approximately 4,500 barrels of Heavy Fuel Oil 7013 (a Bunker C type fuel oil with a high viscosity and an initial density of about 0.99 at lake temperature) and 550 barrels of pole treating oil. About 20% of the released heavy fuel oil (950 barrels) traveled overland and entered Wabamun Lake; no appreciable volume of pole treating oil entered the lake (Hollebone et al. 2011). In the lake, the oil floated and spread rapidly over the lake surface. After a few days, strong winds and wave action dispersed the oil toward the north, east, and south shorelines, where it became entrained in the beds of emergent vegetation (Anderson 2006, Birtwell 2008).*

While traveling overland, the oil mixed with soil and organic matter, and in the lake, OPAs formed quickly, including small tar balls, larger tar "logs", submerged sheets, and large lumps (Fingas et al. 2006; Hollebone et al. 2011). The aggregates showed a variety of behaviors, including submergence, neutral buoyancy, and resurfacing (Fingas et al. 2006), with extensive tar-mat formation in some nearshore areas. The behaviors of this oil in the lake, including rapid formation of tar balls, sinking, slow weathering and degradation due to high proportions of high molecular weight components such as resins, and its toxicity and persistence, were related to characteristics of the heavy fuel oil that would not be directly comparable to most conventional crude oils or diluted bitumen.

Surface sediment (approximately the top 1 to 2 in.) from open water areas was sampled on two dates in August 2005 and analyzed for particle size, total organic carbon, BTEX, PAHs, metals, and other parameters (Anderson 2006). Results were compared with pre-release data from 2002, which had documented some existing PAH concentrations above Canadian sediment quality guidelines due to natural and anthropogenic sources, including exposed coal seams, industrial activity, fossil fuel burning, and leaching from creosote-treated structures. Sediment samples collected from open water areas in 2005 did not indicate the presence of PAHs related to the release, and PAH levels were similar to or lower than those measured in 2002 (Anderson 2006).

Laboratory toxicity tests using the amphipod Hyalella azteca and larval midge Chironomus tentans showed significant toxicity for sediments collected near the release site, but test results were difficult to interpret because test conditions were not the same for all site and control samples (e.g., samples with high sand content had higher mortality, possibly due to sandier habitats not being the preferred by the organisms, or because of the naturally low organic content and food supply in sand) (Lee et al. 2015). Growth of both species and also the aquatic worm Lumbriculus variegatus in both high- and low-sand sediments was significantly lower than in control sediments. In L. variegatus, PAH concentration was correlated with toxicity (Lee et al. 2015).

Using microcosms in the laboratory, biodegradation of oil was tested using sediment collected from Lake Wabumun, to which was added either Bunker C oil recovered from the lake or a reference light oil (Alberta Sweet Mix Blend). Tests were run at 22°C for four weeks and at 4°C for eight weeks (Foght 2006; Wang et al. 2011). Microbes in the sediment were able to degrade a substantially greater proportion of the reference oil than the Bunker C oil, which was attributed to the low proportion of low molecular hydrocarbons and the high proportion of components that do not readily biodegrade (including high molecular weight components such as resins) in the Bunker C oil.

***Pine River, British Columbia**: On August 1, 2000, a pipeline belonging to Pembina Pipeline Corporation ruptured and released approximately 6,200 bbl of sour light crude oil, of which approximately 2,800 bbl entered the Pine River in British Columbia (BC MOE 2000a). The Pine River has a moderate gradient and is swift and clear-flowing. Crude oil was dispersed up to 50 miles downstream (Lee et al. 2015). The fast flowing water allowed rapid dispersion of acutely toxic fractions of the oil into the river water.*

Oil was stranded and settled in depositional areas along the banks, in back eddies and other slow-flowing areas, and on organic debris and logjams (AMEC 2001 in Lee et al. 2015). Heavy rainfall later in August and September mobilized stranded oil, oil-contaminated debris, and sediments downstream, and high water levels scoured some of the more heavily oiled depositional areas. Over a two month period, about 91% of the released oil was recovered or accounted for. It was estimated that the equivalent of approximately 563 bbl was lost to evaporation. A further 523 bbl was unaccounted for and assumed to have been dissolved, adsorbed in soils, deposited to sediments, and/or trapped in backwaters, eddies and logjams (Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015).

Some of the emergency response activities (e.g., removal of logjams and woody debris, altering of backchannels, bank armoring, and presence of heavy machinery in the river) also resulted in habitat damage (Summers 2004 in Bustard and Miles 2011). Of note, prior to the August 2000 release, a small release of diesel fuel (151 barrels) and gasoline (187 barrels) from a tanker truck had occurred in August 1994 in the same area of the Pine River (Goldberg 2011).

Following the release in August 2000, petroleum hydrocarbons were detected chemically and seen and smelled in river water up to 50 miles downstream of the release, with sheen visible in back eddies and other calm areas along shorelines. Hydrocarbons accumulated in sediments and on organic debris (e.g., branches, leaves, and algae) that had accumulated along the shoreline, in front of logjams, and attached to sweeper logs in these calm areas (Lee et al. 2015).

Concentrations in water decreased rapidly to below British Columbia water quality guidelines due to evaporation, dissolving in water, and natural dispersion, occurrences characteristic of light crude oil (Lee et al. 2015). Analysis of semi-permeable membrane devices deployed in the Pine River indicated that two years after the release, hydrocarbons were present in water, implying that hydrocarbons from the release were leaching out of sediment into the water column (De Pennart et al. 2004), although additional sources (e.g., PAHs from coal deposits) in the watershed were also acknowledged. Observations of oil on sediment were made five years after the rupture, although the location and extent were not described (Goldberg 2006 in Bustard and Miles 2011).

***Asher Creek, Missouri**: In August 1979, a pipeline burst, releasing approximately 9,500 barrels of an unspecified type of crude oil into Asher Creek, in southwest Missouri, during low flow conditions (Crunkilton and Duchrow 1990). A responsible party has not been identified for this incident. Dissolved oxygen, pH, and conductivity levels in water were not changed by the release (no information about hydrocarbons in water was published).*

Oil that entered substrates in riffle areas due to mixing was observed for over a year post-release (Crunkilton and Duchrow 1990). The creek originates in springs 0.4 mile upstream of the release. Low water volumes in these headwaters, particularly during summer, provided limited dilution of the oil, increasing the residence time of soluble oil components in sediment (Crunkilton and Duchrow 1990). Areas downstream from surface skimming siphon dams were less severely affected and recovered more rapidly than areas where the substrate became covered with oil (Crunkilton and Duchrow 1990).

7.1.2.5.3 Expected Effects of Released Oils

The main effects of oil deposited on substrates of lakes or watercourses are changes in sediment quality and changes in physical habitat associated with weathered oil. The effects on sediment quality typically persist for months or longer because the heavier molecular weight compounds (many PAHs, resins, and asphaltenes) are slow to weather and degrade; these compounds tend to have chronic, rather than acute toxicity to aquatic biota. Effects on physical habitat (from oil stranded on shorelines and sediment (e.g., as tar balls or OPAs) can also persist, and constituents in the deposited oil can dissolve into the water column over time, resulting in ongoing toxicity to aquatic organisms.

The effects on sediment vary, depending on characteristics of both the oil and environmental conditions at the time of the release. Relevant oil characteristics include density, volatility, solubility, and adhesion, which affect behavior of oil in the aquatic system and weathering of the oil. Environmental characteristics that affect behavior and fate of the oil include water flow, hyporheic flow, dissolved oxygen, and sediment grain size.

If there is a naturally high sediment load in a river (e.g., during a freshet) or if the oil travels over land and picks up soil and organic matter before entering the water, OPAs can form. These aggregates can reach densities that are heavier than water and sink to the bottom in slower flowing areas of rivers. Temperature can affect the rate of sinking, as lower temperatures result in greater viscosity and density, and slower rates of volatilization and biodegradation (Lee et al. 2015), which can favor sinking.

In rivers and streams, there are both erosional (fast flowing) and depositional (slow flowing) areas. Oil tends to accumulate and persist in the depositional areas (inside bends of meanders, backwaters, shoals, pools). Changes in water levels and current velocity can re-suspend the oil, making it available in the water column. In erosional habitats, flushing and fast weathering processes result in faster depletion of the oil compared to the slower rates in depositional habitats, which can be exacerbated if the oil enters anoxic layers of fine sediment. Lake substrates often are predominantly fine sediments, and oil can settle or be stranded on shorelines, shallow areas, and, if the oil combines with particles, in deeper areas.

Organic carbon and pore water presence affect the bioavailability of contaminants in sediment (Enbridge 2014). Organic carbons such as humic and fulvic acids can bind contaminants and render them less bioavailable. Sediment pore water, which is the water present between the particles, can act as a pathway for exposure to dissolved contaminants for aquatic biota.

A release of diluted bitumen is expected to result in effects similar to those for other heavy crude oils. Diluted bitumen does not separate into diluent and bitumen components when released (Taylor et al. 2014; Zhou et al. 2015; Fingas 2015a). It floats on water and can be stranded on shorelines. If the oil first travels over land, it can pick up soil and organic matter, then form OPAs, which can sink, A high proportion of diluent (e.g., condensate) will evaporate quickly and some will be dissolved in the water column and degrade relatively quickly. The residual oil components (PAHs, heavier alkanes, etc.) will degrade more slowly.

Environmental standards for petroleum hydrocarbon residues in sediment are limited. Di Toro et al. (2000), Di Toro and McGrath (2000), and USEPA (2003) developed the equilibrium partitioning sediment benchmark approach that is used to assess the potential toxicity of PAHs, either as individual substances or as mixtures. The same approach has also been applied to the toxicity of fresh and weathered crude oils (Di Toro et al. 2007) and refined oil products (McGrath et al. 2005). This approach, however, demands detailed understanding of the hydrocarbon chemistry.

Empirical approaches are also helpful. Routine analytical laboratory detection limits for total petroleum hydrocarbon (TPH) in sediment typically range from about 2.5 to 15 ppm (or mg/kg). Assuming that crude oil is deposited to the surface of the sediment and mixed into a thin surface layer (less than .25 in.) of sediment that has a high water content, then the mass of oil that is deposited to sediment can roughly converted to a concentration basis in the surface sediment layer. These concentrations can then be related to likely environmental effect levels, based on a variety of studies that examined relationships between TPH concentrations in sediment and

benthic community response (Nance 1991; Rozas et al. 2000; Pettigrove and Hoffmann 2005; Anson et al. 2008).

- Crude oil deposition of less than 0.1 g/m^2 sediment would result in a surface sediment TPH concentration less than 10 ppm, and would be scarcely detectable in routine chemical analysis, and unlikely to have an ecological consequence.
- Crude oil deposition of less than 1 g/m^2 sediment would result in a surface sediment TPH concentration less than 100 ppm, and would be unlikely to result in detectable biological effects.
- Crude oil deposition of less than 5 g/m^2 sediment would result in a surface sediment TPH concentration less than 500 ppm, which could result in adverse effects to a limited number of sensitive species, but could also increase overall benthic community productivity due to an enrichment effect.
- Crude oil deposition of less than 20 g/m^2 sediment would result in a surface sediment TPH concentration less than 2,000 ppm, which would be expected to cause reduced benthic community diversity, biomass and productivity.
- Crude oil deposition of greater than 20 g/m^2 sediment would be expected to cause progressively more serious reductions in benthic community diversity, biomass and productivity.

Table 7-20 provides a summary of how oil characteristics may affect the expected type and scope of environmental effects of crude oil releases on sediment. Table 7-21 considers relationships between environmental characteristics these environmental effects.

Table 7-20 Effects of Oil on Sediment by Oil Characteristic

LAND COVER RECEPTOR: Sediment				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Comments**
Density	Low density crude oils; will float on water. Floating can keep light crude oil away from sediment, but this may change with mixing or changes in density. In the 2000 Pine River, British Columbia release, the light crude oil was well dispersed in river water.	Intermediate in density between light and heavy crude oil; will float on water. Floating can keep medium crude oil away from sediment, but this may change with mixing or changes in density.	Pipeline tariffs require density of diluted bitumen to be less than 0.94. Fresh heavy crude oil and diluted bitumen will float, but may sink with prolonged weathering, or formation of OPAs.	The density of crude oil or diluted bitumen increases with weathering. Density is correlated with viscosity, so that light oils tend to have low viscosity.
Viscosity	Low viscosity oils are readily dispersed in water by turbulence or waves. Dispersal as fine droplets can promote formation of OPAs if other conditions (e.g., suspended sediment concentration, salinity) are favorable.	Intermediate in viscosity between light and heavy crude oils. However, medium crude oils tend to remain within the "low viscosity" range.	Heavy crude oils and diluted bitumens tend to have higher viscosity, although they must still meet requirements for transport by pipeline. With increasing viscosity, and particularly when weathered, diluted bitumens may float on water but resist entrainment as fine droplets except under extremely turbulent conditions.	Crude oil viscosity increases with weathering.
Solubility	Light crude oils typically contain a large fraction of relatively water soluble low molecular weight hydrocarbons. Dissolved hydrocarbons can become adsorbed onto organic matter or suspended sediments and eventually become deposited to sediment.	Intermediate in proportions of soluble low molecular weight hydrocarbons.	The fraction of soluble low molecular weight hydrocarbons depends upon the oil type. Conventional heavy crude oils may have relatively few water soluble components. However, diluted bitumens contain diluent which may (e.g., condensate) or may not (e.g., synthetic crude oil) contain a large component of relatively water-soluble hydrocarbons.	Undiluted bitumen is a naturally highly weathered material, containing few water-soluble components. However, diluent added to bitumen may contain a large amount of relatively water soluble hydrocarbons.
Adhesion	Light crude oils have low adhesion, and form thin layers	Intermediate properties between light and heavy	Heavy conventional crude oils and diluted bitumen have high adhesion,

Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Comments**
	that may weather quickly when the contact solid surfaces.	crude oils.	and can be difficult to remove after they contact solid surfaces.	

Table 7-21 Effects of Oil on Sediment by Environmental Characteristic

LAND COVER RECEPTOR: Sediment				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Sediment grain size	Fine-grained sediments (clay, silt) may resist penetration by oil, particularly when water-saturated. However, if suspended in the water column, fine grained sediments may interact with oil droplets to form OPAs, which may be deposited to sediment in slow-moving areas of water.	Medium-grained sediments (fine to coarse sand) may resist entry of OPAs, particularly if water saturated.	Oil and OPAs can enter pore spaces between coarse-grained sediments (e.g., gravel, cobble), and can become trapped and persist. On the other hand, these sediment types are often found in areas where water currents or wave action are energetic, which can also help to flush and disperse crude oil residues.	Crude oil interactions with sediment are complex. However, long-term deposition of crude oil to sediment is most likely to occur in conjunction with OPA formation, with deposition occurring in areas of slow-moving water and soft/fine-grained sediment.
Water Flow	In slow flowing or still water, crude oil will likely remain floating at the surface. Interactions between crude oil and sediment will be dominated by interactions with shorelines, which are often coarse-grained or armored.	Rivers with moderate flows can transport oil downstream. Mixing can cause dispersion or submersion of crude oil, particularly if it has low viscosity. Crude oil that submerges is likely to re-surface. Interactions between dispersed oil droplets and suspended sediment depend upon the concentration of suspended sediment, and salinity.	Fast flowing waters are typically turbulent, increasing the likelihood of crude oil dispersion as fine droplets. These waters may or may not contain high levels of suspended sediment.	Suspended sediment levels in streams typically increase during periods of high water flow. However, not all fast-flowing streams have high levels of suspended sediment. Higher levels of salinity increase the potential for OPA formation.

Table 7-21 Effects of Oil on Sediment by Environmental Characteristic

LAND COVER RECEPTOR: Sediment				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Suspended Sediment	Low levels of suspended sediment (e.g., <10 ppm) limit the potential for oil-particle interactions and deposition of crude oil to sediment.	Medium levels of suspended sediment (e.g., 10 to 100 ppm) are also likely to limit the potential for oil-particle interactions, particularly where salinity is low.	Oil particle interactions are most likely to occur where suspended sediment levels are high (e.g., >100 ppm).	True oil-particle interactions require a combination of suspended sediment, as well as sufficient turbulence to disperse crude oil as fine droplets in the water column. Salinity also promotes these interactions.
Dissolved oxygen	Low oxygen environments may occur in lakes or deep, slow-moving depositional areas of rivers. Low oxygen availability limits aerobic biodegradation of oil. Anaerobic degradation of oil can occur, but rates are slower than for aerobic processes.		High oxygen environments (saturated or super-saturated) can occur in high gradient streams where water turbulence results in greater entrainment of oxygen. These high oxygen environments can facilitate aerobic biodegradation of crude oil that may be trapped in interstitial spaces of gravel and cobble.	Oxygen is typically a not limiting factor to biodegradation in rivers, except in deep, slow moving areas or in sediment pore water. Oxygen becomes a limiting factor to biodegradation in areas of depositional sediment. Crude oil deposited in anoxic sediment may persist indefinitely.

Table 7-21 Effects of Oil on Sediment by Environmental Characteristic

LAND COVER RECEPTOR: Sediment				
Environment Characteristic	**Low**	**Medium**	**High**	**Comments**
Hyporheic Flow (water exchange between the river and bed sediment)	Rivers are generally areas of groundwater inflow. In these areas, natural groundwater flow into the river will prevent crude oil residues from entering the hyporheic zone.	Irregular river bed surfaces can create local pressure gradients so that fine-scale interactions driven by hydrostatic pressure may draw water into the river bed, trapping small droplets of oil in the bed sediments.	In steep terrain, hyporheic flow systems may occur on river reach scales, with water entering the river bed near the start of riffles, and exiting in riffle tail pools. In arid environments, rivers may feed water into the regional groundwater flow system on an even larger scale, so that entrained oil droplets would be transported into the river bed on a larger scale.	Oil entering the hyporheic zone can become trapped in the sediment by adsorption to particles or can contaminate interstitial water. These areas are often important for benthic community production, or as spawning or juvenile rearing habitat for fish. Hyporheic flow is more likely in areas of coarse-grained sediment than fine-grained sediment. Continual flushing of the hyporheic system or periodic spate events will typically restore habitat quality.

7.1.2.6 Shoreline and Riparian Bank

7.1.2.6.1 Receptor Description

Shoreline and riparian areas are lands adjacent to lakes, ponds, streams, and rivers where soils and vegetation are strongly influenced by the presence of water and exposure stresses such as waves, flood flows, elevated water tables, scour, erosion, and sediment movement (Boak and Turner 2005). As a result, these areas frequently support a diverse set of environmental processes and associated plant communities adapted to disturbance regimes over varying spatial and temporal scales (Keddy 1982; Keddy 1983; Wilson and Keddy 1986; Gregory et al. 1991; Strayer and Findlay 2010).

Shoreline and riparian areas may have various substrate types (e.g., organic material, sand, silt, clay, gravel, cobble, rip-rap, and cement). Shoreline slopes may range from gentle inclines to steep or undercut, depending upon the prevailing hydraulic regime and landscape they occur in. Plant communities range from types characteristic of exposed beaches, rocky shorelines, and unconsolidated shorelines, to densely vegetated emergent and marsh wetlands, and forested riparian lands. Such communities contain plant species that are adapted to the various combinations of physical gradients and exposure that occur at a particular location (Keddy 1982; Keddy 1983; Wilson and Keddy 1986; Shipley et al. 1991). Communities change over time as physical conditions and competitive interactions are modified by climactic patterns and variations in disturbance stresses (Keddy and Reznicek 1986; Gaudet and Keddy 1995; Boak and Turner 2005; Strayer and Findlay 2010).

Shoreline and riparian areas provide a variety of functions that are valuable to humans. Examples of such ecosystem services include support of fish, wildlife, and non-game species; water quality buffering; flood flow dissipation; erosion protection; and aesthetic quality. Shoreline and riparian areas are often destinations for people seeking to enjoy activities such as fishing, swimming, and boating. Shoreline habitats are at risk from oil releases because of the high likelihood of being directly oiled by floating slicks, or by deposition of oiled debris, tarballs, or other oil aggregates.

Shorelines vary from place to place, based on landform, exposure, and plant community development, making classification a complex undertaking. Most classification systems are based either on the physical characteristics of the shore or on some combination of physical characteristics and vegetation (Reid and Holland 1997). In general, freshwater shoreline types can be placed into the following categories (Owens et al. 1993; NOAA and API 1994):[9]

1. Sand—sandy shorelines are areas where most particles are between 0.003 and 0.079 in. (0.075 to 2 mm) in diameter. Such shorelines may consist of one size of sand or a mixture of different sand sizes with elements of clay, silt, gravel and cobble. Often sandy shorelines

[9] Particle sizes are converted to Imperial measure based metric standards from ISO)publication 14688-1:2002, Identification and Classification of Soil.

have varying amounts of woody and other debris. Plants tolerant of disturbance may grow in areas of stable sand with adequate organic material, moisture, and nutrients.

2. Mixed Sand and Gravel—these shorelines are composed of varying amounts of sand and gravel with particle sizes ranging from 0.00079 to 2.5 in. (0.02 mm to 63.0 mm). Varying amounts of wood and other organic debris may be present. Plant communities tend to be minimal on mixed sand and gravel shorelines due to high levels of disturbance and poor water holding capacity. However some hardy plants may grow in relatively sheltered locations.
3. Gravel/Cobble—gravel shores are dominated by material with particle sizes ranging from 0.079 to 7.9 in. (2 to 200 mm). Scattered larger sized boulders, patches of sand, woody and other debris may also be present. Plant communities tend to be minimal on gravel shorelines due to high levels of disturbance and poor water holding capacity. Some hardy plants may grow in relatively sheltered locations.
4. Bedrock—bedrock shores are composed of impermeable rocky substrate that may be intact or contain cracks, fissures, and crevices. Such shores can range from vertical walls to nearly flat shelves. In most cases bedrock shorelines have limited associated biological communities and human uses, although cliff structures can provide nesting and foraging areas for birds, and some plants may grow where pits and cracks provide rooting opportunities and sufficient moisture.
5. Vegetated banks—vegetated banks are non-wetland areas occurring on mineral or organic soils at and just above the ordinary high water level. Vegetation generally consists of species found in adjacent upland communities, although specialist species such as alders, willows, and cottonwood trees may predominate. Field crops, grassland, or lawns may be present in developed areas. Many animal species use these areas for foraging, nesting, and hiding. Some animals such as swallows and muskrats may also create nests by burrowing into banks.
6. Mud/Sediment—med/sediment shorelines are composed primarily of silt and clay particles (<0.00079 in. or <0.02 mm). They may be intermixed with areas of sand and gravel and generally occur in areas of low exposure. Woody and other debris may be present. Often these areas are high in organic content and support diverse communities of plants and invertebrates.
7. Wetlands—in some locations, the shorelines of lakes, ponds, rivers, and streams are not clearly defined and the aquatic system may transition into a wetland. Depending upon the associated hydrology and plant community type, wetlands may be described as bog, marsh, fen or swamp subtypes.
8. Manmade Structures—manmade structures include shore protection surfacing such as seawalls, bulkheads, riprap revetments and groins, breakwaters and jetties, which may be constructed of rock, concrete, wood, and/or corrugated metal or plastic. Manmade structures usually have specific human use, but may have limited associated value as biological habitat.

The following summary of observed and expected effects of released oil to shoreline and riparian areas considers the non-wetland areas described above. Wetlands are addressed separately in Section 7.1.2.7.

7.1.2.6.2 Observed Effects of Oil along Shoreline and Riparian Areas

Although there are few published reports, data available from field experiments and a small number of freshwater case studies provide a basis for describing what happens to shoreline and riparian areas following a crude oil release, and for categorizing the relative sensitivity of

different shoreline types. The overall pattern in these published records is that the key determinants of oil effects to shoreline and riparian areas include the type and quantity of oil released, the type of water body affected, the shoreline type and complexity, and the vegetation community type present (Gundlach and Hayes 1978; Baca et al. 1985; Owens et al. 1987; NOAA and API 1994; Hossler et al. 2007; Michel et al. 2008).

Oil type can influence the fate of released oil because crude oils and petroleum products are composed of differing mixtures of hydrocarbon compounds. Each substance has physical properties (e.g., viscosity, adhesion, density, solubility) that reflect its chemical composition and affect its fate and transport once released into the environment (NRC 2003). Light, low viscosity oils are generally retained on shorelines only as thin layers of oil, which will also weather quite rapidly (Curl and O'Donnell 1977; Davis et al. 2004). In contrast, heavy oils tend to be viscous adhesive, so they tend to be retained on shorelines as thicker layers of oil. Heavy oils exposed to sunlight and wave action weather to form tar balls and other deposits that can be difficult to remove from shoreline rocks and sediments (Atlas 1975; Overstreet and Gault 1995; USEPA 1999; Ansell et al. 2001). Heavy oils also contain larger amounts of substances such as resins and asphaltenes, which weather slowly and render them more persistent than light oils.

The Grapevine Creek oil release in Kern County, California and the Chalk Point oil release into the Patuxent River, Maryland demonstrate the differences between oil type and persistence. The Grapevine Creek release consisted of approximately 6,200 barrels of San Joaquin valley light crude entering a small stream. Sampling data indicated that within two days of the release a majority of the oil had dissipated and over 90% of its toxic compounds were gone (Mancini et al. 1995). In contrast, the Chalk Point oil release consisted of 3,333 barrels of No. 6 heavy fuel oil that ran into Swanson Creek and the Patuxent River. In this case, sampling indicated that within the first five days of the release 39% of the oil had dissipated and the residue remained substantially toxic (NOAA et al. 2002).

The type of waterbody also influences the effects of released oil on shorelines and banks by affecting oil concentration, retention time, flushing rate, and the potential for emulsification and weathering (Baca et al. 1985; NOAA and API 1994; Overstreet and Gault 1995; Owens 2003). In general standing water bodies such as lakes and ponds will have lower physical removal, dilution and flushing rates, and slower weathering of crude oil than moving water such as rivers and streams (Baca et al. 1985; NOAA and API 1994; Overstreet and Gault 1995). In rivers and streams, higher mixing rates may also increase contact between oil and suspended sediments, promoting enhanced biodegradation rates through oil-mineral aggregate formation (Lee 2002; Owens and Lee 2003).

Differences in effect related to the water body type are illustrated by the Marathon oil release into Newton Lake, Illinois, and the tank ship MOBILOIL release into the Columbia River. The Marathon release occurred on April 27, 1985, releasing approximately 10,775 barrels of Southern Louisiana crude oil into the north end of Newton Lake in Jasper County, Illinois. The oil moved slowly along the lake surface allowing retention of most of the oil within about a mile of the

release site, although a period of high winds dispersed a small amount past the booms and several miles further south(Sauer et al. 1995; Neff et al. 1995). Shoreline oiling occurred primarily in areas near the release, where wind pushed oil toward the lake edges. In locations farther away from the release site, winds and water currents retained oil on the water surface (Sauer et al. 1995; Neff et al. 1995). In contrast, the MOBILOIL incident released over 3,900 barrels of heavy fuel oil into the Columbia River near St. Helens, Oregon on March 19, 1984. High river flows rapidly carried the oil downstream as surface and subsurface material. After 24 hours, material was detected over 50 miles downriver (Kennedy and Baca 1984). After 48 hours the oil reached 70 miles downstream and entered the convergence zone with the Pacific Ocean. Shoreline oiling above the convergence zone was related to fluctuations in river water level and much of the deposited material was rewashed into the river during subsequent high water events (Kennedy and Baca 1984).

Substrate type (e.g., grain size, mobility, organic content), substrate motility, slope and exposure, and type of vegetation can influence the effects of released oil on shoreline and riparian areas (Gundlach and Hayes 1978; Little and Scales 1987; Humphrey et al. 1993; NOAA and API 1994; Rayburn 2001; Peterson et al. 2002; Short et al. 2004; Owens et al. 2008). The degree of oil penetration into the shoreline substrate depends in large part on the permeability of the substrate (Etkin et al. 2007). There is an interaction between crude oil viscosity and average substrate pore size that determines oil retention capacity. Shoreline substrates that are water-saturated or can maintain water saturation during periods of low water level (e.g., clays, silts, and muds) are resistant to penetration by crude oil. Shoreline substrates that drain down and are porous may be penetrated by crude oil; however, light crude oils with low viscosity may be poorly retained by coarse open substrates such as gravels and cobbles, whereas heavy crude oils with higher viscosity may penetrate and be retained within such substrates. Retention of crude oil in shoreline substrates can increase the complexity and intrusiveness of the clean-up (Li and Boufadel 2010).

Sub-surface or sequestered crude oil may become physically protected from disturbance, oxygenation, and photolysis, only partially weather, and retain some degree of contamination for years (Peterson et al. 2003). Fine sands and muddy sediments have the lowest permeability of unconsolidated types and also tend to be water saturated, so oil penetration is very limited. On the other end of the scale, gravel and cobble substrates are highly permeable. Consolidated shoreline materials such as bedrock, and some manmade materials such as concrete or sheet pile, tend to be impermeable except where cracks, fissures, and other similar features occur.

The importance of shoreline exposure and slope is their effect on wave frequency, magnitude, and action (Owens et al. 1987; Little and Scales 1987; Little et al. 1993; Owens and Lee 2003; Short et al. 2004; Etkin et al. 2007). In lakes, shorelines that are exposed to prevailing summer winds (lee shores) tend to be washed by waves, while windward shorelines are generally calmer. Steep shoreline areas are usually subject to abrupt wave run-up and breaking, and even reflection in places, which enhances natural clean-up of the shoreline. Flat shoreline areas, on

the other hand, promote dissipation of wave energy farther offshore, which lets oil remain longer in the shoreline zone.

In rivers, the situation is more three-dimensional but the basic concepts still pertain. As Owens (2003) pointed out, "[g]enerally, the waters of a river move in one direction (downstream) but locally within a channel there are back eddies, whirlpools, and other dynamic hydraulic features that alter the simple unidirectional flow pattern". Once oil enters this dynamic environment, the rate of movement is primarily a function of river flow. It thus tends to be deposited along shorelines in quieter waters where velocity and turbulence decrease at a given river stage rather than along shorelines more exposed to strong currents (Kennedy and Baca 1984; Baca et al. 1985; Owens 2003).

Where dense vegetation exists at the land-water interface and released oil approaches from the water, the vegetation can provide a barrier and protect shoreline resources from contact with substantial amounts of oil. One example of this was reported following the 1988 Shell Oil release in Martinez, California. In this release, nearly 9,405 barrels of San Joaquin Valley crude oil was released into Peyton Slough and Shell Marsh. Researchers found that, in shoreline areas with vegetation, a majority of the oil was absorbed by the vegetation and did not reach soil to the landward side (Fraser et al. 1989). Similarly, shoreline oiling data from the November 2000 M/T Westchester oil release into the Mississippi River showed that along vegetated shorelines oiling occurred usually as a narrow band along the outer fringe, with little penetration into the vegetation and minimal contact with the shoreline substrates (Michel et al. 2002, 2003).

In cases where the oil reaches the shoreline from land or where waterborne oil penetrates the vegetation, shoreline plants can increase the shoreline's oil-holding capacity and oil residence time, thereby resulting in a greater duration of oiling effects than in similar un-vegetated shorelines (Gundlach and Hayes 1978; Baca et al. 1983; NOAA et al. 2002; Peterson et al. 2003; Michel and Rutherford 2013). The trapping capacity of vegetation is illustrated by the May 1983 oil release near Wilmington, North Carolina that released approximately 119 barrels of waste heavy fuel oil into the Cape Fear River (NOAA 1997). The oil affected approximately 30 miles of high-marsh type shoreline dominated by species of *Spartina, Scirpus,* and *Juncus.* Studies five months after the release found that the vegetation trapped oil along the shoreline from which it continued to seep at low tide (Baca et al. 1983). A study of the September 1969 oil release into Buzzard's Bay near West Falmouth, Massachusetts reported that oil residues persisted in the marsh vegetation along the shoreline, but not elsewhere in the release zone (Peacock et al. 2005).

The time of year of a release can influence the resulting effects to shoreline and riparian areas by determining sensitivity of affected resources and the ease of detection and clean-up. Oil released when plants are beginning to grow or reproducing result in greater damage than when plants are dormant. Oil releases in winter and under ice, however, can make detection and clean-up difficult, prolonging the period of oiling (Telford and Quam 1979; Owens et al. 2005).

7.1.2.6.3 Expected Effects of Oils on Shoreline and Riparian Areas

The expected effects of oils in shoreline and riparian areas mirror the observed effects reported in published literature. The magnitude of effects depends on three principal dimensions, namely oil type, shoreline type, and degree of exposure to physical processes

The review of case studies above indicates that in general, the lighter the oil, the more impervious the substrate, and the more exposed the site, the less will be the effect. Thus, a light oil released in a shoreline area consisting of bedrock or concrete with high exposure can be expected to have relatively minor shoreline effects, while a heavy oil released into sheltered shoreline areas with diverse wetland vegetation can be expected to have more severe effects. Assuming a release of an equivalent amount of the same type of oil, the relative sensitivity of different shoreline habitats to the oil can be generally ranked from low to high as shown below (adapted from NOAA and API 1994; Jensen et al. 1998; Peterson et al. 2003; Etkin et al. 2007):

1. Exposed rock cliffs, seawalls, and other exposed, impermeable vertical shorelines
2. Exposed bedrock shelfs, shoals, and ledges, concrete slopes, and other impermeable, non-vertical shorelines
3. Moderately exposed fine-grained sand beaches, eroding sediment scarps and banks, and other semi-permeable, shorelines
4. Moderately exposed coarse-grained sand beaches, sandy bars, sloping sand banks, and other moderately permeable shorelines
5. Moderately exposed mixed sand and gravel beaches, bars, sloping banks and other moderately to highly permeable shorelines
6. Moderately exposed gravel beaches, bars, and sloping banks; rip-rap, and other highly permeable shorelines
7. Moderately exposed soft mud and mixed mud/sand flats and other flat, semi-exposed, semi-permeable shorelines
8. Sheltered, moderately sloping rock, mud, or clay banks; rip-rap or rock rubble, vegetated bluffs and other impermeable shorelines
9. Sheltered sand/mud flats, vegetated low banks and other flat, semi-Permeable shorelines
10. Sheltered organic flats supporting marsh, swamp, and other diverse wetland shorelines

Effects of released crude oil on riparian areas are consistent with effects of released oil on wetlands, soils and terrestrial vegetation communities, as discussed elsewhere. Riparian areas are transitional between water and land, and subject to seasonal cycles of inundation and drainage that depend strongly upon site-specific conditions of hydrology, soil type and vegetation community present.

7.1.2.6.4 Summary of Oil Release Effects on Shoreline and Riparian Areas

Table 7-22 and Table 7-23 provide a summary of the expected environmental effects of oil releases to shorelines. Table 7-22 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-23 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-22 Effects of Oil on Shoreline and Riparian Areas by Oil Characteristic

Oil Characteristics	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—adhesion	Light crudes have low adhesion properties that require less intensive remediation efforts to remove oil from shoreline and riparian areas	Medium crudes have moderate adhesion properties that require more intensive remediation than light crudes, but less intensive than heavy crudes, to remove oil from shoreline and riparian areas.	Heavy crudes have high relative adhesion rates that require intensive remediation efforts to remove oil from shoreline and riparian areas. Diluted bitumens initially have similar adhesion properties, but through weathering become more adhesive than weathered conventional heavy crudes.	The adhesive properties of oils change with weathering as the more soluble and less viscous constituents evaporate to the environment. Adhesion is also related to the viscosity and persistence of oil and is specific to the particular type of crude oil.
Oil properties—viscosity	Light crudes have a low relative viscosity and are more readily disperses in aquatic environments than medium and heavy crude oils. Thus, they have a greater potential to affect larger extents of shoreline and riparian areas.	Medium crudes have a moderate relative viscosity and tendency to disperse in aquatic environments. Thus, they have a moderate potential to affect shoreline and riparian areas.	Heavy crudes have a high relative viscosity and lower tendency to disperse in aquatic environments. Diluted bitumens when fresh have lower viscosity than heavy conventional crudes; however, the viscosity of diluted bitumen increases rapidly with weathering. Heavy crudes and diluted bitumens have a lower potential to affect larger extents of shorelines and riparian areas as the released oil tends to remain aggregated, but oil is also likely to be deposited more thickly than for lighter crudes.	Viscosity of crude oils increases with weathering as low molecular weight components that act as solvents evaporate rapidly.

Table 7-22 Effects of Oil on Shoreline and Riparian Areas by Oil Characteristic

Oil Characteristics	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—persistence	Light crudes tend to be deposited more lightly, and have a lower persistence in the environment due to their more volatile constituents (i.e., low molecular weight hydrocarbons) and smaller proportions of persistent components (e.g., resins and asphaltenes). Therefore, light crude oils tend not to be persistent, and affected shoreline and riparian habitats are likely to recover quickly.	Medium crudes have a moderate relative persistence in the environment due to their mixture of volatile and non-volatile constituents. Therefore, there is a moderate potential duration of effects to shorelines and riparian areas from released hydrocarbons.	Heavy crudes and diluted bitumens are likely to be deposited more thickly, and contain larger proportions of resins and asphaltenes than lighter crude oils. Heavy crudes are therefore more persistent in the environment. Shoreline and riparian areas affected by heavy crude oils will take longer to recover than similar areas affected by lighter crude oils.	Persistence in the environment is assessed here without taking into account oil spill response, including clean-up and removal of released hydrocarbons. Oil spill response activities would enhance natural recovery, reducing although not eliminating differences related to crude oil type.

Table 7-23 Effects of Oil on Shoreline and Riparian Areas by Environmental Characteristic

Environmental Characteristics	Low	Medium	High	Other Comments
Ice cover	Ice-free conditions permit contact between released oil and shoreline/riparian areas. Recovery of hydrocarbons from open-water environments is simpler and more effective, reducing potential for crude oil contact with shorelines.	A release to the aquatic environment during spring break up creates challenging conditions for recovery efforts. Hydrocarbons are likely to contact shoreline and riparian areas. High water levels would promote entry of released oil into flooded areas and riparian zones.	A release to the aquatic environment under ice cover creates challenging conditions for recovery efforts. However, ice cover may limit crude oil contact with shorelines, and prevent contact with riparian areas. Hydrocarbons released onto ice covered aquatic environments or frozen shorelines are more easily recovered and tend to have less substantial effects to shorelines and riparian habitats.	A release under winter ice may be followed by a "secondary release" as oil that was trapped under the ice is mobilized with spring breakup and rising water levels.
Shoreline slope	Steep shorelines are usually subject to abrupt wave run-up and breaking, and even reflection in places, which enhances natural clean-up of the shoreline.	Moderate slope shorelines have intermediate risks of oil retention.	Flat or gentle slope areas promote dissipation of wave energy further offshore, letting oil remain longer in the shoreline zone. In sheltered habitats, slope is a less important factor with regard to oil effects, except that biological communities have more area to develop, and may represent more important units of habitat, where the slopes are gentle.	Shoreline slope is a factor that would be more important in large lakes than in many other freshwater habitats.

Table 7-23 Effects of Oil on Shoreline and Riparian Areas by Environmental Characteristic

Environmental Characteristics	Low	Medium	High	Other Comments
Shoreline exposure	Low energy shorelines and are sheltered from wave energy, except during unusual or infrequent events. Weathering and flushing rates are low and oil can remain adhering to the shoreline for extended periods of time. Sheltered areas also tend to have conditions conducive to development of relatively diverse biological communities making them more sensitive than locations that have greater exposure.	Medium energy shorelines have intermediate characteristics with respect to oil deposition, weathering, flushing, and retention.	High energy shorelines are regularly exposed to large waves or strong currents. The effects of oil on exposed habitats are reduced because: 1) offshore-directed currents generated by waves reflecting off hard surfaces push the oil away from the shore; 2) wave and/or current-generated forces mix and rework shoreline materials that are typically coarse-grained, removing stranded oil; and 3) organisms adapted to living in high energy settings are accustomed to short-term perturbations in the environment.	
Shoreline composition	Impermeable shorelines largely impermeable to oil except when it is able to enter crevices or fractures in rock surfaces. Impermeable shorelines tend to retain less oil, for shorter periods of time, than permeable shoreline types.	Moderate permeability shorelines have intermediate risks of oil penetration, burial, and retention.	Highly permeable shorelines tend to retain more oil and may sequester crude oil in relatively fresh form for longer periods of time. If the substrate pores are large and inter-connected, the substrate will be more permeable and allow deeper penetration and even lateral movement through capillary action.	Water saturation of shoreline substrates can prevent ingress of crude oil.

Table 7-23 Effects of Oil on Shoreline and Riparian Areas by Environmental Characteristic

Environmental Characteristics	Low	Medium	High	Other Comments
Riparian area	Watercourses occupying incised channels with narrow riparian areas present smaller surface area and lower habitat value to be harmed by retained or entrapped crude oil residues.	Watercourses having moderate riparian zones present intermediate surface area and habitat values to be harmed by retained or entrapped crude oil residues.	Watercourses having broad floodplain areas may represent important and rich habitat units, where effects may be more extensive and damaging to biodiversity than in less extensive floodplain areas.	

7.1.2.7 Wetlands

7.1.2.7.1 Description

Wetlands are areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support a vegetation community that is typically adapted for life in saturated soil conditions. Three key diagnostic environmental characteristics are therefore used to define wetlands (Environmental Laboratory 1987):

- Soils are present and are classified as hydric, possessing characteristics that are associated with reducing or anaerobic soil conditions
- Area is flooded, either permanently or periodically, with shallow water; or the soil is water-saturated to the surface at some time during the growing season of the prevalent vegetation
- Prevalent vegetation consists of macrophytes that are typically adapted to areas subject to flooding, and that have the ability to thrive in anaerobic soil conditions

Wetlands develop through the recurrent or prolonged presence of water at or near the soil surface, which greatly influences associated soil development and the types of plant and animal communities living in the soil and on its surface (Heimlich et al. 1998). Wetlands provide a variety of ecosystem services of benefit to humans, including the following functions and values that have been identified as important to the people of Minnesota (MN DNR 1997):

Table 7-24 Identified Functions and Values

Wetland Functions	Wetland Values[1]
1. Hydrologic Flux and Storage: includes ground water recharge and discharge; stream discharge and recharge; water storage, and evapotranspiration export. 2. Biological Productivity: includes primary productivity; secondary productivity; carbon storage; and carbon fixation. 3. Biogeochemical Cycling and Storage: wetlands can be a nutrient source or sink, an area for oxidation and reduction chemical transformations; an area for dentrification; and reservoirs for sediment and organic matter. 4. Decomposition: involves carbon release; mineralization; detritus output for aquatic organisms; and release of chemical compounds. 5. Community Wildlife Habitat: providing habitat for algae, bacteria, fungi, insects, invertebrates, wetland plants, fish, shellfish, amphibians, reptiles, shorebirds, waterfowl, and other wildlife. Wetlands are often critical habitat for rare and unique species enhance the diversity and resilience of plant and animal communities.	• Water supply and low flow augmentation [A] • Flood water retention [A,B] • Water quality protection [A,B,C] • Sediment control [A,C] • Wastewater treatment [B,C] • Nutrient removal [B,C] • Shoreline anchoring and erosion control [A,B,C] • Education and research [A,B,C,D,E] • Historical and archeological resources [B,E] • Open space [A,B,E] • Aesthetics [A,E] • Recreation [A,E] • Hunting and trapping [B,E] • Plant and animal refuges [E] • Threatened and endangered species habitat [E] • Crop (e.g., hay) and pasture [A,B] • Timber production [A,B] • Peat production [B,C,D] • Shrub crops (e.g., cranberry) [A,B] • Wild rice gathering/production [A,B] • Food production/aquaculture (fish, game) [B,E] • Medical product production (streptomycin) [D,E]

Table 7-24 Identified Functions and Values

Wetland Functions	Wetland Values[1]
NOTE: [1] Bracketed letters indicate influencing wetland functions identified in the first column.	
SOURCE: adapted from MN DNR 1977	

Wetlands generally include bogs, fens, marshes, swamps, and similar areas, and may be bordered by areas that are either wetter (e.g., open water or lake habitats where vegetation is no longer a dominant feature of the environment) or drier (e.g., transitional and upland areas where the water table is rarely at the ground surface, flooding is infrequent, and soils are not hydric).

Minnesota contains seven types of native wetland communities that provide the functions and values listed above to the benefit of individuals, communities, the state's citizens, and the overall integrity of land and water systems. Summary descriptions of these seven wetland communities are presented below. The focus in this section is primarily on plant community type and site hydrology.

7.1.2.7.1.1 Bogs

Bogs are nutrient-poor late-successional communities characterized by the prevalence of sphagnum mosses and ericaceous shrubs (heath family). Bogs have a raised water table relative to the surrounding landscape, and the bog water is classically isolated from deeper groundwaters because of the peat accumulation. Most water and nutrients are derived from rainfall, and bog waters are acidic (Bay 1968; Boelter and Verry 1977).

There are two general bog community types in central and northern Minnesota: forest bog and open bog (Aaseng et al. 1993; MN DNR 1997). Both types have a nearly continuous mat of moss dominated by *Sphagnum* species (especially *Sphagnum fuscum* and *Sphagnum angustifolium*), and an impoverished vascular plant flora. The ground layer is dominated by low ericaceous shrubs (e.g., Labrador tea, leatherleaf, swamp laurel, or bog-rosemary), sedges (*Carex* spp.), or cotton grasses (*Eriophorum* spp.). The forest bog community also has a tree layer dominated by black spruce.

Bogs are very sensitive to changes in hydrology and surface and peat water chemistry. Alterations to these parameters can result in shifts in species composition and associated reductions in community quality (Wilcox 1986; MA DFW 2007; Karofeld et al 2008).

Phytoplankton communities of bog pools are typically species-poor, tending to be dominated by filamentous green algae, acidophilous diatoms, and desmids (USEPA 2002a, 2002b). Algal diversity tends to be greatest in open-water areas and in systems connected to other lakes or streams (Wehr and Sheath 2003).

7.1.2.7.1.2 Fens

Fens include community types that occur on wet mineral or peat soils with seasonally standing or flowing water at the ground surface (Aaseng et al. 1993; MN DNR 1997). Fens are further divided into three sub-types according to water chemistry and associated plant community (poor fen, rich fen, calcareous seepage fen). Generally, they occur on sites too wet for significant invasion by woody species, or on sites that burn frequently. Fens share the general characteristic of a closed canopy of mid-height graminoids (grasses or grass-like plants). Dominant species include grasses (e.g., bluejoint (*Calamagrostis canadensis*, prairie cordgrass (*Spartina pectinata*), sedges (e.g., wiregrass sedge (*Carex lasiocarpa*), lake-bank sedge (*Carex lacustris*), tussock sedge (*Carex stricta*), and rushes (e.g., *Scirpus cespitosa*). Fens may have associated algal communities generally dominated by green algae, cyanobacteria, and alkaliphilous diatoms (USEPA 2002a, 2002b; Rober et al. 2013).

7.1.2.7.1.3 Marshes

Marshes are shallow-basin wetlands that develop in standing water typically in mineral soils or in relatively inorganic sediments associated with lakes, ponds, and streams (Aaseng et al. 1993; MN DNR 1997). Marsh vegetation is composed of tall, erect, rooted graminoids such as cattail (*Typha latifolia* and *T. angustifolia*), common reed grass (*Phragmites australis*), bulrush (*Scirpus* spp.), rush (*Juncus* spp.), spike-rush (*Eleocharis* spp.), and some sedges (*Cyperus* spp.). Common herbs associated with marshes include broad-leaved arrowhead (*Sagittaria latifolia*), swamp milkweed (*Asclepias incarnata*), willow-herb (*Epilobium* spp.), bulb-bearing water-hemlock (*Cicuta bulbifera*), and knotweed (*Polygonum spp.)*. Obligate aquatic plants (including *Potamogeton*, *Elodea*, *Ceratophyllum* and *Myriophyllum*) often are present in the standing water of marshes. Algal communities are also important components of marsh wetland ecosystems, contributing significantly to ecosystem primary production and nutrient retention, which improves water quality (Wehr and Sheath 2003; Rober et al. 2013). Wild rice, a commercially and culturally important species grows in some emergent marshes, and in shallow bays of lakes, generally in water less than about three feet deep, in areas with slow current, over a mucky or silty sediment, with little competition from other plants (Moyle 1944; Tucker et al. 2011).

7.1.2.7.1.4 Swamps

Shrub swamps are minerotrophic, tall-shrub communities occurring on mucks and shallow peat soils dominated either by alders (alder swamps) or willows (willow swamps) (Aaseng et al. 1993; MN DNR 1997). The major shrub species in these communities are usually alders (*Alnus* spp.), willows (*Salix* spp., and red-osier dogwood (*Cornus stolonifera*). Common understory species in the community include tussock sedges (*Carex* spp.), cattail (*Typha latifolia*), blue-joint (*Calamagrostis canadensis*), northern marsh fern (*Thelypteris palustris*), jewel-weed (*Impatiens capensis*), and mosses (e.g., *Sphagnum squarrosum*). Shrub swamps are typically non-stagnant wetlands with high levels of dissolved oxygen and soil nitrogen. Soils range from poorly drained to well drained, with most sites remaining saturated throughout the growing season.

Conifer swamps tend to develop on sites with wet mineral or poorly drained organic soils. There is often standing or barely moving water within the community (Aaseng et al. 1993; MN DNR 1997). The tree canopy is dominated by black spruces, tamaracks, or white cedars. The density of the shrub, herb, and moss layers varies greatly, depending on the density of the tree canopy, soil nutrients, and the level of the water table. Due to anaerobic conditions associated with a high water table and organic soils, trees growing in conifer swamps are shallowly rooted. The understory of the community commonly contains combinations of speckled alder, winterberry, red-osier dogwood, willow species, and mountain fly honeysuckle. On less acidic sites, groundcover includes blue-joint, cattail and jewel-weed, while more acidic sites are characterized by a continuous hummocky mat of sphagnum mosses with bog birch, leatherleaf, other ericaceous species, cinnamon fern (*Osmunda cinnamomea*), and various sedges.

Hardwood swamp forests are minerotrophic wetland communities that occur on muck and shallow peat substrates on wet sites in depressions on level to hummocky glacial lake plains, fine- and medium-textured glacial tills, and broad flat outwash plains (Aaseng et al. 1993; MN DNR 1997). Standing water, usually a result of groundwater seepage, is usually present in spring and drained by late summer. Hardwood swamps have tree canopies dominated by broad-leaved deciduous species, including black ash, paper birch, yellow birch, red maple, American elm, slippery elm, green ash, quaking aspen, or, rarely, balsam poplar. Understory vegetation may include alders, ferns, a variety of herbs, sedges and mosses. Areas of standing water will also contain populations of floating and submerged algae.

7.1.2.7.1.5 Other Related Habitat Types

Wetlands are often associated with streams, rivers and lakes, and intergrade with other recognized habitat types around these features.

Floodplain forest is a bottomland, deciduous or deciduous-conifer forest community occupying riparian areas subject to periodic over-the-bank flooding and cycles of erosion and deposition (Aaseng et al. 1993; MN DNR 1997). Floodplain forests are generally dominated by silver maple, cottonwood, black willow, American elm, green ash, and bur oak. Due to frequent flood disturbance, the understory of floodplain forest is often relatively open, with few tree seedlings and saplings. Shrubs may be a significant component, particularly where canopy gaps occur. Woody vines, including wild grape (*Vitis riparia*), poison ivy (*Rhus radicans*), and Virginia creeper (*Parthenocissus quinquefolia*), are often present in light gaps and along open channels. The herbaceous layer generally has low diversity, and contains only short-lived species or species otherwise tolerant of frequent disturbance, such as wild-rye (*Elymus virginicus*), cleavers (*Galium aparine*), sedges (*Carex* spp.) and nettles (Urticaceae).

Vernal pools are small isolated pocket wetlands that occur in depressions located within forested settings. These depressions, typically in mineral soil with an underlying impermeable clay layer, collect water in the spring from runoff and precipitation then dry out later in the year as water inputs decline below evaporation and infiltration rates (Batzer et al. 2004; Brooks 2004; Leibowitz and Brooks 2007; Palik et al. 2007; Thomas et al. 2010). Vernal pools may occur in all

forested community types but are most common in wet forest types with poorly-drained mineral soils and least common in dryer forests with generally sandier, more well drained soils (Leibowitz and Brooks 2007; Thomas et al 2010). Plants that grow in vernal pools are often tolerant of flooding, soil saturation, and drought.

7.1.2.7.2 Observed Effects of Oil on Wetlands

The effects of oil on the plants, soils, and water comprising wetlands have been evaluated in laboratory and field experiments, experimental oil releases, and case studies of accidental oil releases. These data sources span marine, freshwater, terrestrial, arctic, and temperate environments; upland and wetland vegetation; and controlled and uncontrolled settings. Most of the experimental spills and accidental oil release case studies include clean-up and remediation efforts. The body of published studies provides a framework for projecting the effects likely to result from releases of oil into different types of wetlands.

Oil affects wetlands by damaging one or more of their primary components: vegetation, soil, and water. Oil can affect wetland communities directly by blocking metabolic processes and indirectly through changing a plant's internal chemistry or by altering soil characteristics and/or water chemistry. The damage can vary considerably based on several factors. Effects vary based on the time of year, the amount of water flow through the community, water chemistry, abundance of oil, type of oil, and type of release (Michel and Rutherford 2013). The toxicity of an oil depends largely upon its content of aromatic compounds (hydrocarbons containing benzene rings), oxygenated aromatic derivatives, and aliphatic compounds (hydrocarbons without benzene rings). Lighter oils, though more acutely toxic than heavy oils, also undergo more rapid weathering leading to a reduction in toxicity. Heavy oils, while potentially having lesser acute toxicity, also weather more slowly, often resulting in longer persistence in the environment.

When released into water, oil spreads over a wide area forming a slick and immediately begins to undergo a variety of physical, chemical, and biological changes including evaporation of high volatile fractions, dissolution of water-soluble fractions, photochemical oxidation, emulsification, microbial degradation, and sedimentation. These processes are affected by temperature, wind speed, and water chemistry and may vary across different types of wetland habitats. Releases into wetlands will tend to be more confined, and the associated effects more concentrated than in open waters of large bodies of water (Shales et al. 1989). Smaller freshwater wetland environments can also be more sheltered from the effects of wind than larger lakes, resulting in lower rates of physical weathering. The effects of crude oil released to lakes are discussed in Section 7.1.2.3.

Oil that directly contacts plants can impede photosynthesis and gas exchange processes by blocking sunlight, clogging stomata, and raising internal temperature (Baker 1970; Emerson 1983; Michel and Rutherford 2013; Pezeshki et al. 2000). When these conditions are of sufficient extent and duration, the loss of metabolic processes result in a decline in vitality, and eventually, if not reversed, death. While light hydrocarbons such as gasoline, diesel fuel, gas condensates and

light crude oils can "burn" green plant tissues, resulting in tissue death and in some cases death of the whole plant, heavier crude oils may coat the plant tissues and cause death by smothering.

Changes to wetland soil or sediment characteristics that can be caused by crude oils include alterations to soil chemistry affecting nutrient availability, decreased water content due to increased repellency, and associated changes to vegetation and soil organisms (De Jong 1980; Emerson 1983; Hemmings et al. 2015). Oil flow into the soil or sediment can cause plant mortality by killing root tissues, restricting the availability of nutrients, and/or preventing regrowth from rhizomes (Corn and Copeland 2010). Because crude oil deposited in wetlands alters the microbial process, there can be a subsequent change in soil or sediment biochemistry (Nyman 1999; Mendelssohn et al. 2012). The presence of crude oil typically causes a decrease in microbial diversity and an increase in abundance of those microbes that can more readily use the carbon source available in the oil. This change in the microbial community can ultimately modify nitrogen cycling dynamics within the wetland, affecting plant growth and associated processes (Plice 1948; Ellis and Adams 1961; Greer et al. 2003).

Following a release of 30,000 barrels of crude oil into a Louisiana cypress swamp, researchers observed plant growth in affected and in unaffected control areas (Baca et al. 1985). According to the researchers:

> Comparisons of control and affected sites one year following the release showed that areas with high shading by cypress, sweetgum, and tupelo had little or no understory and very few effects were seen on the dominant woody vegetation. In addition, perennials (e.g., *Pontederia cordata*) were returning in all sunlit areas. However, floating vascular vegetation suffered significant impacts. Areas of water in the swamp once completely covered by water hyacinth (*Eichhornia crassipes*, an introduced pest) and associated nonvascular plants were devoid of any vegetation.

Following the 1972 release of approximately 160 barrels of diesel fuel into a wet meadow near Mount Baker, Washington, studies were made of the initial effects of the oil on the vegetation and of community recovery over nine years (Belsky 1982). The studies concluded that:

> Both the amount and the type of the oil in the Mt. Baker oil release were responsible for the initial impact which reduced vegetative cover from nearly 100% to less than 1% and all species except *Phyllodoce empetriformis, Carex lenticularis,* and *Rhacomitrium sudeticum* had died. The added burden of a large volume of oil (160 barrels) flowing through a small area increased the damage. The snow cover, steep terrain, and snowmelt water, on the other hand, reduced the impact of the diesel oil on the meadows. In the Mt. Baker release, oil flowed over frozen and saturated soils and contacted dormant vegetation. Most of the diesel oil flowed down the steep slope and out of the area instead of pooling for

> later absorption. In the summer a large volume of snowmelt water flushed much of the oil out of the area. Recovery of the habitat began with seed germination of *Carex nigricans* within one year, followed by seedlings of other common subalpine species two to four years later. Nine years after the perturbation 5 to 20% of the ground was covered with vegetation and the original disturbance could no longer be discerned by a casual observer.

After approximately 24 barrels of fuel oil released into a freshwater marsh along the Mill River near Northampton, Massachusetts researchers followed the growth of vegetation over four years (Burk 1977). The vegetation bad been studied the year prior to the release and, less intensively, three years previously. Following the study, researchers reported that:

> Total plant cover, total number or species, mean number of species per quadrat and the Shannon-Wiener function progressively reduced in both high and mid-marsh zones for two years after the release. Eighteen of the species found before the release were not found the following season. Perennial species generally were less affected than annual species immediately following the oil release. Some species (e.g., *Dulichium arundinaceum and Eleocharis palustris)* declined in abundance the second season following the release. Marked changes in relative abundance of the dominant species of high and mid marsh zones occurred from year to year, with *Onoclea sensibilis* more prominent in high marsh at the end of the study period than prior to the release and *Pontederia cordata* and *Nuphar variegatum* more prominent in different segments of mid-marsh. The vegetation of the high marsh and mid-marsh zones had substantially recovered by the third and fourth years. The low marsh vegetation was apparently unaffected immediately following the oil release but in succeeding years the species diversity declined and luxuriant growth of *Elodea nuttalii, Potomogeton crispus,* and *Potomogeton epihydrus* occurred.

Hutchinson and Freedman (1978) studied the effects of experimental releases of crude oil into a boreal conifer swamp using spray and point discharges. Following the study, they reported that:

> Spray releases of fresh unweathered crude oil at an intensity of 2 gallons per square yard had a general herbicidal effect, causing the death of any green tissue coming in direct contact with the oil. Death of lichens and mosses was rapid and complete. For some higher plants, a lag period (up to 4 years for some individuals of *Picea mariana*) occurred between the time of the release and the time of death. For others, death occurred during the first winter with marked effects on cover values in the spring. These effects resulted in large decreases in total plant cover and frequency at release sites. However, within a few weeks, and in subsequent years, some species developed regrowth shoots. Other species survived as underground rhizomes for a number of years prior to their reappearance above ground (i.e., *Equisetum scirpoides*). Limited seedling

> establishment by vascular plants was first observed in the fourth growing season after the release, when some sporeling establishment was also noted for several bryophyte species. No *Picea mariana* regeneration occurred in the release plots in six post-release growing seasons. Crude oil releases made in winter were found to be less damaging than equivalent summer releases in their short term biological effects and on rates of recovery and species affected. Initial observations indicate that a summer diesel oil release shows roughly equivalent toxicity to a summer crude oil release of the same intensity. Comparisons between an intensive release (53 barrels) made at one location and dispersed spray releases indicate that the former are less damaging per unit of oil, with the scale of adverse effects being related more to the area of contamination.

Racine (1994) studied the same sites 10 years later, and reported that:

> Low volume spray releases that uniformly covered the ground caused initial damage to vegetation, but after 20 years recovery of the understory vegetation was almost complete, with dramatic recovery and expansion of fruticose lichens. High volume point releases created small areas of surface oil saturation with dead vegetation and little sign of recovery, but spread out mostly below ground with little or no apparent effect on the shallowly rooted vegetation even after 15–20 years. Because winter point releases created a much greater area of surface oil, their effects were more damaging. After 15 years on the saturated surface oiled areas, only *Eriophorum vaginatum* tussocks survive and grow. At both sites with surface oil, black spruce mortality was high, with no evidence of long term recovery and with continuing chronic effects after 15 years.

Leck and Simpson (1992) studied the effects of crude oil contaminated soil on plant growth recruitment from the seed bank from two tidal freshwater wetlands along the Delaware River in New Jersey. The authors observed that:

> Oil treatment of marsh soils significantly reduced survival of *Acnida cannabina* and *Bidens laevis,* the dominant species, as well as number of species per sample and height of *B. laevis.* Total perennial seedlings, present in low numbers, also showed significant reduction with treatment. However, during the course of the study, *Peltandra virginica* recruitment and survival were not reduced by soil oil treatments and recruitment of *Sagittaria latifolia* appeared enhanced.
>
> The effect of oil on recruitment from the seed bank depends on: (a) the extent to which it covers the wetland soil thereby acting as a physical barrier to water and oxygen, (b) the extent to which it penetrates and remains in the soil thereby either coating the seeds or being toxic to them, and (c) blocking the ability of germinated seeds to reach above the soil surface.

> Oil releases can have significant short-term effects on seedling establishment and growth that may translate into long-term effects on composition. If a release were to eliminate recruitment and reproduction of annual species, we feel that species with persistent seed banks and ability to germinate throughout the growing season, such *as A. cannabina* and *B. laevis,* or perennials with widespread and summer dispersal, such as *Typha* spp. or *P. arundinacea,* could colonize gaps as they occur. Others such *as P. virginica* and *S. latifolia* with more tolerant seed/seedling characteristics may reinvade more quickly than annuals.

Lin and Mendlssohn (1996) studied the effect of south Louisiana crude oil on the dominant vegetation, *Spartina alterniflora, Spartina patens and Sagittaria lancifolia,* of three types of coastal wetlands, salt, brackish and freshwater marshes, respectively. In a greenhouse, the crude oil was applied to natural marsh sods at rates of 0, 0.88, 1.77, 3.53 and 5.30 gallons/square yard. After measuring plant growth for a year, the researchers concluded that:

> The present study clearly demonstrates that South Louisiana crude oil, when applied to the soil, significantly impairs the two *Spartina* species, while not adversely impacting *S. lancifolia.* The sensitivity is based on the effect of oil on photosynthetic rate, live and dead biomass, plant-stem density, and plant regrowth in the year following oil application. The differential oil sensitivity was partially related to differences in soil organic matter among the marsh-types. The soil organic matter played a key role in accelerating penetration and sorption of oil into the soil. The soil organic matter content, therefore, is a primary factor controlling the effects of oil releases in marshes, as initially hypothesized. Oil releases in marshes of high organic matter content may require particular concern. The plant responses observed were also related to differences in the plant sensitivities to oil.

7.1.2.7.3 Expected Effects of Oil on Wetland Community Types

The summaries below provide a general description of the type of effects that may be expected from an oil release in a given wetland type, absent clean-up, based on the wetland hydrology, soil/sediment type, plant community type. However, each oil release is different with effects that vary depending on the quantity and type of oil released, the characteristics of the affected area, the time of year and the climate/weather conditions prevailing at the time of the release.

7.1.2.7.3.1 Bog

Bogs are susceptible to oil damage due to the predominance of low stature plants with high surface area to mass ratios and shallow roots (Aaseng et al. 1993; MN DNR 1997). Plants of this type would be readily exposed to released oil. Due to the generally low topographic gradient, spongy substrate and slow-moving water, oil released into a bog would likely pool. While this would result in smothering and death of most plants it came into direct contact with, it would also limit the area affected. Subsequently, and following clean-up, vegetation in and around the release would likely be affected by altered water chemistry and nutrient availability, as well

as by residual effects of low hydrocarbon concentrations. Light oil released into a bog would likely have more severe short-term effects (due to its lower viscosity and greater tendency to spread horizontally) but less severe long-term effects than heavy oil, which would spread less, but be more persistent if not physically removed. Some plant mortality may be expected along with longer term stress and growth reductions until residual hydrocarbons in the peat and water weathered sufficiently to abate toxic stress. Medium weight oils are expected to exhibit intermediate effects consisting of some smothering and moderate toxicity damage. Changes in water chemistry from the persistence of oil or oil fractions in the bog could potentially encourage the growth of plants such as cattail and reed grass that prefer less acidic conditions and/or are tolerant of persisting hydrocarbon compounds (Werner et al. 1985; King and Coley 1985; Shales et al. 1989; Crowe et al. 2002).

7.1.2.7.3.2 Fen

The wet meadow/fen wetland types are highly susceptible to damage from released oil. Oil released to a fen (where groundwater is expected to be discharging, and the soil surface is water saturated) would spread across the surface of the wetland, contacting ground-level vegetation. Some oil would also likely be incorporated into the soil surface (Hemmings et al. 2015). For heavy oils, the combination of smothering, toxicity, and changes in water chemistry would likely result in plant mortality along with persistent inhibition of regrowth as long as un-weathered oil remains (McCown and Deneke 1972; Leck and Simpson 1992; Hemmings et al. 2015). Woody shrubs would be less likely to be affected.

7.1.2.7.3.3 Marsh

Marshes appear moderately susceptible to damage from released oil, with floating plants in proximity to the release point being more susceptible to damage than larger emergent plants with a small portion of their mass at or below the water and/or away from the oil flow path. Oiling of only the stems of emergent plants often results in limited mortality. If only the aboveground vegetation is oiled, regrowth is likely during the next growing season (Baca et al. 1985; Fraser et al 1989; Mancini et al. 1995; Michel et al. 2002, 2003).

Releases of light refined or crude oils which spread rapidly and have higher acute toxicity can result in high mortality of marsh vegetation. Effects would be more persistent in cases where oil penetrates into marsh soils (Mancini et al. 1995; Davis et al. 2004). Persistence increases with deeper penetration, soils high in organic matter, and sites that are sheltered from natural removal processes (Peterson et al. 2003; Etkin et al. 2007). Heavy oils that coat the entire plant, and particularly the leaves, have the greatest potential for widespread damage. Plants with leaves at or near the water level will be most affected by smothering, while taller plants may suffer dieback, reduced growth, or remain unharmed.

For marshes associated with lakes, less damage would be expected for releases into water or along the outside marsh fringe where natural removal processes from wind and wave exposure are more effective. In this case, plants in shallower water closer to the shore might remain protected and experience little or no damage (Fraser et al. 1989; Michel et al 2002, 2003).

Conversely, a release from shore is likely to result in the greatest exposure to crude oil residues (and correspondingly more severe effects) in the near-shore zone (Gundlach and Hayes 1978; Baca et al. 1983; NOAA et al. 2002; Peterson et al. 2003; Michel and Rutherford 2013).

7.1.2.7.3.4 Swamp

Swamps appear to be moderately susceptible to damage from crude oil exposure. In general, the predominant vegetation is woody and moderately tolerant of crude oil exposure due to the presence of bark which is protective of living tissues beneath. The slow water flow in swamps means that oil released into these systems tends to remain stagnant, limiting the area affected but prolonging contact and potentially exacerbating toxicity in the affected area (Baca et al. 1985; Shales et al. 1989). Shallow rooting structures make plants growing in these areas more susceptible to damage and long-term effects from changes in soil communities and chemistry. A release of light crude oil would likely result in death of ground cover, with less damage to shrubs and herbaceous vegetation in areas of higher relief. In the case of a release of heavy oil, mortality of herbaceous plants and smaller woody plants from smothering and toxicity would be expected, and if not remediated, potential damage to trees and larger shrubs from changes to soil and water quality and the uptake of hydrocarbons through roots and bark (Atlas 1975; Curl and O'Donnell 1977; Davis et al. 2004). Lost productivity and reduced reproduction from plants that do not die is likely (Currier 1951; Dallyn 1953; Baker 1970; Emerson 1983).

The general effects of oil released to a conifer swamp would be similar to, but somewhat more pronounced than the effects of a spill on a hardwood swamp. Black spruce appears particularly sensitive to the presence of crude oil in the root zone (Hutchinson and Freedman 1978; Racine 1994). Therefore, greater potential for tree mortality, growth suppression, and inhibition of regrowth are likely for all types of crude oils although there may be a time-lag between the initial release and mortality of larger trees. Some effects to germination and vegetative reproduction may also occur in the area of the release where seeds, tubers, and rhizomes are damaged (Burk 1977; Leck and Simpson 1992; Adam and Duncan 2002). Where oil persists in the community, regrowth is likely to be suppressed for an extended period until the oil substantially weathers and toxicity abated.

Shrub swamps appear to be moderately susceptible to damage from an oil release. While alders, willows, and dogwoods have an ability to reproduce vegetatively, their prevalent lenticels and shallow rooting habit in this community make them susceptive to intake of toxins and root damage from direct contact and dissolved hydrocarbon compounds. Short-term contact with light oils would likely result in mortality of most herbaceous plants and smaller shrubs. Larger shrubs and those on hummocks may survive but suffer reduced growth (Burk 1977; Belsky 1982; Mancini et al. 1995). Medium and heavy oils would likely cause the mortality of most plants in and around the release. Lighter oils would likely cause some mortality of herbaceous plants and small shrubs and reduced growth rates of the larger shrubs but likely not cause complete mortality except perhaps at the point of release (Atlas 1975; Curl and O'Donnell 1977; Davis et al. 2004). Some effects to germination and vegetative reproduction may also occur in

the area of the release where seeds, tubers, and rhizomes are damaged (Burk 1977; Leck and Simpson 1992; Adam and Duncan 2002).

7.1.2.7.3.5 Other Related Habitat Types

Floodplain forest wetlands appear moderately susceptible to damage from oil releases. In general, these communities are composed of larger woody vegetation that is protected by bark, limited herbaceous plants, and common natural disturbances such as flood events that can accelerate flushing, dissipation, and weathering (Currier 1951; Dallyn 1953; Baker 1970; Emerson 1983; Baca et al. 1985). The most severe effects would be from extensive releases of heavy oil. In this scenario, hydrocarbons could coat herbaceous and small woody vegetation to the point of severe stress or mortality, become incorporated into the soil, or settle in ponding areas where it could persist, causing changes to soil and water quality until the oil had substantially weathered and substantively abated in toxicity (Atlas 1975; Curl and O'Donnell 1977; Davis et al. 2004). Less severe effects would be expected for smaller releases or releases of light crude oil where the material may coat or stain vegetation, but rapidly weather. In these cases initial plant mortality may still occur, but soil incorporation or persistent changes to water quality are less likely, although residual effects may occur from portions of the light oil that do not volatilize. Some effects to germination and vegetative reproduction may also occur in the area of the release where seeds, tubers, and rhizomes are damaged (Burk 1977; Leck and Simpson 1992; Adam and Duncan 2002).

A vernal pool could present as a shallow depression in the landscape that could trap released oil during the summer, fall and winter seasons, or as a shallow standing water body in the spring. Oil released into a vernal pool in the spring would be trapped in a relatively small amount of water resulting in minimal dilution and high toxicity to aquatic life (typically insects, crustaceans, mollusks, and amphibians, but not fish), and potentially waterfowl. Crude oil residues would likely become incorporated into the soils when the pool dried up. During dry periods, released oils would collect within the pool depression without any dilution. Light petroleum oils would weather more rapidly than heavier ones but in both instances some fractions of the oil would likely be incorporated into the soil being remobilized when the pool flooded again. Regardless of timing, petroleum oils released into a vernal pool would be expected to cause mortality of herbaceous species and algae as well as shrubs and smaller trees as a consequence of capture and concentration within the pool. Some larger trees and shrubs around the edge of the pool may survive but experience decreased growth and reproduction for several years (Burk 1977; Belsky 1982; Mancini et al. 1995). Growth from seeds, tubers, and rhizomes trapped under residual heavy oil would also likely be inhibited both from oil-related chemicals and the smothering cover (Burk 1977; Leck and Simpson 1992; Adam and Duncan 2002).

7.1.2.7.4 Summary

Table 7-25 and Table 7-26 provide a description of the general relative environmental effects of different types of oil and wetland characteristics. Table 7-25 addresses the relative effects of

specific oil characteristics or oil type on wetlands, and Table 7-26 addresses the relative influence of different environmental characteristics on wetlands exposed to oil releases.

Table 7-25 Land Cover Receptor: Wetlands

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Viscosity	Low viscosity oils are more readily absorbed into plant tissues, causing acute damage. Low viscosity oils also have less tendency to adhere to plants and to persist in water and sediment resulting in relatively lower long-term chronic damage.	Intermediate effects based on specific oil constituents.	Greater tendency to adhere to plants causing smothering and greater tendency to sink and persist in water and sediment causing long-term chronic toxicity damage.	Low viscosity oils may spread over larger areas than higher viscosity oils which form thicker but less spatially extensive slicks. Viscosity is also correlated with adhesion and pour point temperature of crude oils.
Proportion of VOCs	Light crude oils generally contain relatively more VOCs, and may have greater acute toxicity to plants as a result.	Intermediate acute toxicity.	Lower acute toxicity due to crude oil chemical properties, but this may be offset by higher viscosity and greater tendency to adhere as a thicker coating on plant tissues.	Some diluted bitumens (e.g., winter blends that contain a large amount of condensate as diluent) may have similar VOC content to light crude oils.
Persistence	Light crude oils tend to have low persistence due to a predominance of chemical constituents that will readily weather, and low concentrations of relatively persistent constituents such as resins and asphaltenes	Intermediate persistence properties.	Heavy crude oils contain relatively more resins and asphaltenes than light crude oils, and these constituents tend to be persistent (i.e., are resistant to microbial and other weathering processes) in the environment.	Heavy crude oils also tend to have high viscosity, and would tend to be deposited more heavily, but over a smaller area, than lighter crude oils.

Table 7-26 Land Cover Receptor: Wetlands

Environment Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Plant type—annual, perennial, shrub, tree	Annual and perennial herbs are most sensitive to oil exposure, and particularly sensitive to light crude oils; shrubs and trees are less sensitive. Light crude oil would be less persistent than heavier crude oils, so long-term or chronic effects on wetland vegetation are less likely.	Effects of medium crude oil are likely to be intermediate between the effects of light and heavy crude oils.	Heavy crude oil is expected to be more adhesive, coating more thickly, but affecting a smaller overall area than lighter crude oils. Heavy crude oil is also likely to persist at higher concentrations in wetland soils and sediments, leading to higher potential for long-term or chronic effects on vegetation.	At low levels of exposure, oiling may kill only the green tissues of plants, with regeneration occurring in the same growing season. At higher levels of exposure, annual and perennial plants and shrubs may be killed outright, and trees may die over the course of several growing seasons.
Wetland type—bog, fen, marsh, swamp	Bogs and fens tend to lack a free water surface, and released oil will follow preferential flow paths according to site-specific topography. This can limit the spatial extent of effects, while facilitating recovery of pooled oil. Marshes and swamps typically have a free water surface that will promote the spreading of released oil, leading to effects over larger areas, and making recovery of released oil more difficult.			
Season	A crude oil release in spring (plant emergence/early growth period) would tend to result in greater mortality of small plants, new plants, and annuals, particularly if growing tips and leaves were contacted by fresh crude oil. A release later in the growing season would have less severe effects on plants where the oil was not in contact with leafy tissues. Effects to wetlands during the winter may be low, if oil can be recovered before spring thaw.			
Ground surface diversity	Hummocky or mounded conditions within a community may allow species growing in locally higher elevations to avoid direct contact with the oil. This would be particularly true in locations where much of the oil presence is transitory (e.g. bogs, fens, swamps and floodplains). Habitat such as vernal ponds formed in depressions where oil would collect are at greatest risk of damage from direct contact and chronic effects from absorption and soil contamination.			
Soil organic content	Soils with low organic content may tend to retain oil constituents for shorter time periods thus resulting in less long-term damage to resident plants. Oil may be more persistent in hydric soils and soils with higher organic matter (where oxygen may would also be limiting) leading to more chronic effects on wetland vegetation. Heavy oils would also tend to be more persistent than lighter oils.			
Wetland hydrology	Wetland habitats with moving water (e.g., marsh and swamp habitats that are marginal to rivers or lakes) allow greater flushing and weathering of released crude oil, while at the same time enhancing the spreading of oil in the environment. Stagnant or ponded areas provide little flushing and less weathering. These habitats would be at greater risk of damage from released crude oil.			

Table 7-26 Land Cover Receptor: Wetlands

Environment Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Water chemistry	Slightly alkaline habitats with high nutrient availability provide better conditions for microbial degradation of released crude oil, particularly for light crude oils that weather and undergo biodegradation more readily than heavy crude oils. More acidic, nutrient-poor habitats would be expected to exhibit slower rates of biodegradation.	Medium crude oils would be expected to exhibit biodegradation rates, and response to water chemistry conditions, intermediate between light and heavy crude oils.	Heavy crude oils tend to be recalcitrant due to their greater resin and asphaltene content. Water chemistry may have little effect on biodegradation rates for heavy crude oils.	Bogs tend to be acidic, with low nutrient availability. Marshes and swamps tend to have greater nutrient availability, but released oil may be deposited to anaerobic areas where biodegradation would be slow. Fens are minerotrophic, and groundwater seepage would tend to prevent oil from penetrating to anaerobic areas. Biodegradation potential in relation to water chemistry and wetland type is expected to improve in the order Bog < Marsh = Swamp < Fen.

7.1.2.8 Soils

7.1.2.8.1 Description

According to the Natural Resource Conservation Service (Soil Survey Staff 2003), soil is a natural material composed of solids (minerals and organic matter), liquid, and gases that occurs on the land surface, occupies space, and is characterized by one or both of the following: (1) horizons or layers that are distinguishable from the initial material as a result of additions, losses, transfers, and transformations of energy and matter; or (2) the ability to support rooted plants in a natural environment."

Soils are open systems that interact with the lithosphere, hydrosphere, atmosphere, biosphere, and society to perform vital ecosystem functions. Major soil functions include (Cornell University 2010):

1. Soil is a medium for plant growth or bio-materials production whereby this medium combines with the other soil functions to anchor roots, and allow for the transport of water and nutrients to the root/soil interface
2. Soil is a habitat for soil organisms, making up more than half of all life on the planet. The micro-organisms are mainly responsible for most of the bio-chemical transformations in the soil medium; whereas, the macro-organisms primarily affect physical soil transformations
3. Soil acts as a biochemical or nutrient reactor which absorbs, releases (i.e., desorbs), and transforms inorganic and biochemical compounds such as essential plant nutrients, pesticides, minerals, heavy metals, and numerous other compounds
4. Soil acts as a hydrologic buffer which stores (i.e., water holding capacity) and regulates the flow (i.e., drainage) of water in the landscape, allowing for the transport of various inorganic and biochemical compounds within and through the soil medium
5. Soil is a foundation for the physical support of structures including everything from plants to skyscrapers

There are numerous types of surface soils, the distribution and characteristics of which are broadly controlled by parent material, topography, climate, biota, and time. Although they are variable, soils typically include a common matrix of mineral and organic particles, water, and gases. This soil matrix directly supports an ecosystem that is commonly made up of microbes, invertebrates, and plants. These organisms in turn, provide a supporting foundation for an even larger ecosystem that includes animals and humans.

Soil microorganisms are an integral part of the soil and include bacteria, fungi, algae, protozoa and nematodes. As a community or assemblage, these organisms are responsible for cycling nutrients such as nitrogen, phosphorous, potassium, calcium, magnesium, iron, and sulfur, through the decomposition of organic matter, which includes oil.

The abundance and diversity of soil organisms depends on the nature of the soil and the associated plant community. A key element regulating these characteristics is the availability of active organic matter that can readily be used by microbes and invertebrates as a source of energy. In addition, oxygen, nutrients, moisture content, temperature and other climatic factors

also play important roles in soil organism community structure and abundance. Root growth is a significant contributor to soil ecosystem development. Of particular importance in microbial ecology is the zone of the soil-root interface known as the rhizosphere. The rhizosphere receives photosynthetic carbon compounds secreted from plant roots. These root secreted compounds, including organic, amino and fatty acids, carbohydrates, vitamins, nucleotides, phenolic compounds, polysaccharides, and proteins, are metabolized by surrounding microorganisms. In turn, the microorganisms mediate biochemical reactions that make nutrients available to plants. Nutrients are also made available as microbes die and decay during the cycle of immobilization and mineralization, which is strongly influenced by the carbon to nitrogen ratio. Where conditions are favorable, soil sustains a high abundance and diversity of microorganisms and invertebrates that occupy a broad and complex range of niches.

7.1.2.8.2 Observed Effects

The following case studies, primarily from temperate North American environments, provide examples of the effects that documented oil releases have had on the soil and soil organisms. In most cases, pipeline releases on land are remediated by scraping or excavating the land surface until desired clean-up targets are achieved. Additional details of some of the releases used as case studies for soils and microorganisms can be found in Stantec et al. (2012) and Enbridge (2015). Each of these releases and how they affected soil resources are described in the paragraphs below.

> ***Unknown Operator, Nipisi and Rainbow Releases, Alberta:*** *During 1970–1972, three oil releases occurred in north central Alberta, Canada near Lesser Slave Lake (Wang et al. 1998). These three releases, located at Nipisi, Rainbow and Old Peace Rivers, occurred within about two miles of one another. Little information is readily available about the Rainbow and Old Peace River releases, but the Nipisi release site has been extensively studied. The Nipisi release was one of the largest releases in Canadian history and involved over 60,000 barrels of crude oil that affected over 25 acres of predominantly bog/fen habitat. A variety of clean-up techniques, including burning, tilling, and fertilizer addition, were applied at the Nipisi site, after which it was left for research to evaluate the effectiveness of these techniques and characterize the weathering of the released oil (Wang et al. 1998).*
>
> *Twenty-five years after the releases, researchers returned to the area to assess the oiling conditions and recovery status. Substrate samples were collected from the 3 release locations: 22 samples from the Nipisi site; 9 from the Rainbow pipeline release; and 3 from the Old Peace River site. Most of the samples consisted of 100% organic materials, sphagnum peat, or a similar peat, and a few of the samples included a mineral component. Samples were grouped based on depth of collection. Surface samples were collected from the upper approximately 1.5 inches. One group of subsurface samples was collected primarily between 4*

and 16 inches below ground surface (bgs), and the second group of subsurface samples came from a depth of 16 to below 31 inches (Wang et al. 1998).

Based upon TPH levels, the surface samples were still highly contaminated (20,000–256,000 ppm) with oil, although the oil was highly weathered/degraded. The subsurface samples collected between depths of 4 to 16 inches also were still highly contaminated (10,000–165,000 ppm), but the oil was only lightly to moderately weathered/degraded. The deeper (34 to 39 inches) subsurface samples were only lightly contaminated (less than 673 ppm) with oil. The analysis indicated that the oil released on the surface had started to weather almost immediately through evaporation, but subsequent weathering through biodegradation and other weathering processes were occurring at a much slower rate. Biodegradation rates were projected to be slow because of the acidic condition of the peat, the anaerobic conditions created by the saturated ground and the relatively cool temperatures. Degradation of the subsurface oil was expected to continue and to be aided by rainfall, which would increase ground saturation and bring the oil to the surface where more aerobic conditions exist and more nutrients are available to aid in biodegradation. The researchers' determination was that the site was recovering, but that this recovery was happening slowly and would continue to happen slowly (Wang et al. 1998) on a scale of decades.

***Unknown Operator, Moose Jaw, Saskatchewan**: In January 1974, a pipeline containing crude oil broke within an active agricultural field just north of Moose Jaw, Saskatchewan. The pipe was buried 3.3 ft below the soil surface, and the asphalt-base oil (23 API gravity, 0.92 grams per centimeter cubed [g/cm^3] density) flowed underneath the frozen topsoil. The release was first detected in a ditch approximately 2,789 ft from the pipeline and later in a small pool approximately 82 ft south of the line. There was also some surface pooling closer to the release, but the majority of the oil was present as a thin lens, a fraction of an inch thick, just below the frost line at 3.3 ft in depth. Because the oil was contained, trenches were dug around the release perimeter, and an estimated 10,000 barrels of the 15,725 barrels of oil were recovered. Further remediation of the affected soil was not conducted, and in the spring of 1974 crops were planted. Fertilizer was applied to enhance the rate of oil weathering, but this was limited to the maximum rate tolerated by the crops. Monitoring of the remaining oil showed that from 1974 to 1978, there was a noticeable decrease in oil content, particularly in the 1977 fallow year when higher levels of fertilizer could be applied (De Jong 1980). The surface soil from 0 to 11.8 inches showed the greatest hydrocarbon reductions. Results of the site study provide further support for the role of microbial-mediated degradation in reducing the concentration of oil in soils, and in the recovery of the environment. According to De Jong (1980), addition of fertilizer helped compensate for the increased demand for nitrogen*

made by the microorganisms, which were most active in the surface soil where there was more oxygen.

Enbridge Line 6, Bemidji, Minnesota: *In 1979, a pipeline released approximately 10,700 barrels of light crude oil in a naturally vegetated area. The oil sprayed over an area of approximately 1.6 acres and collected in topographic depressions before infiltrating the soil and migrating to the groundwater. Although there were immediate effects from the oil on the terrestrial habitat, subsequent burning of the oil sprayed area had a much greater effect on this habitat. The area has remained relatively barren for most of the last 30 years because the soil became water repellent due to the oil contamination and possibly from the burning (Nieber 2013). Using the Water Drop Penetration Time test (Dekker 2009) to assess water repellency of the soil, researchers found that the soil within the oil spray zone ranged from slightly repellent to extremely water repellent. Where the soil was extremely water repellent, the water drops tended to evaporate from the surface before they could be absorbed into the soil. Outside the oil spray zone, the soil was water "wettable." Repellency within the oil spray zone extended to a depth of approximately 16 inches in some locations. A soil erosion survey conducted in this area found that much of the surface soil had eroded from the higher topographic points leaving them very stony. The sand eroded from these higher points was deposited in adjacent topographic depressions (Nieber 2013).*

Line 3 Glenavon, Saskatchewan: On April 15, 2007, an Enbridge Line 3 underground pipeline ruptured near Glenavon, Saskatchewan and released approximately 6,200 barrels of heavy crude oil into a slough (wetland) located in an agricultural area (SLR Consulting 2008a; Transportation Safety Board Canada 2008a). Soil located around the edges of the slough was also exposed to oil. Release response and clean-up efforts included:

- *Repair of the pipe*
- *Recovery of oil from surface water within the affected slough*
- *Deployment of booms*
- *Construction of berms to contain the oil within the immediate area of the affected slough*
- *Removal of oiled vegetation around the perimeter of the affected slough*
- *Removal of water from the affected slough that had hydrocarbon concentrations above applicable criteria, including those established in the Canadian Council of Ministers of the Environment (CCME) Freshwater Aquatic Life Criteria (1999, updated 2007) and/or Saskatchewan Environment*
- *Removal of contaminated sediment and soil*

Recovery of approximately 240,925 gallons (912 m^3) of the released oil was completed by April 22, 2007 (Transportation Safety Board Canada 2008a). Water and crude oil were removed from the affected slough with skimmers and

vacuum trucks. Irrigation sump lines were then used to move the collected water to an on-site above ground storage tank (AST) for temporary storage. Backhoes were used to remove contaminated sediment from the slough and to cut and remove oiled vegetation. Soil from around the edges of the slough also was removed. Contaminated vegetation, sediment and soil were transported to an off-site location for disposal (SLR Consulting 2008a).

As part of the initial Environmental Site Assessment following the release, soil samples were collected in association with four components of the response and clean-up efforts: site stratigraphy boreholes; pipeline trench repair; irrigation sump lines; and remediation of the affected slough. The collected soil samples were analyzed for BTEX, petroleum hydrocarbon fractions F1 to F4 (PHC F1-F4 {F1: C6 to C10, F2: >C10 to C16, F3: >C16 to C34, F4: C34+}), total metals, and Polycyclic Aromatic Hydrocarbons (PAHs). For soil samples not associated with the affected slough, analyses indicated that contaminant concentrations generally were below Saskatchewan Environment and CCME remedial criteria (Tier 1 Agricultural Criteria for fine grained soil; Saskatchewan Ministry of Environment 2006) with the exception of two sites associated with the irrigation sump lines. Additional excavation was conducted at these two sites, and subsequent sampling indicated that the criteria were met. Concentrations of metals for all these samples either were below CCME agricultural criteria or were consistent with background conditions (SLR Consulting 2008a). Subsequent sampling along the pipeline trench identified some locations where PAH concentrations were above remedial criteria. These areas were further excavated and, as a result, all post remediation soil samples were below CCME remedial criteria (SLR Consulting 2008b).

For the affected slough, estimates were that any remaining crude oil effects after the initial remediation efforts likely were limited to the sediment and possibly the upper 1 ft of underlying native clay soil. Additional remediation efforts were undertaken to remove sediment and native clay soil under the affected slough that had hydrocarbon concentrations exceeding applicable remedial criteria (SLR Consulting 2008b). Following additional remedial actions PAH concentrations were below CCME criteria and BTEX and F1-F4 concentrations from the base of excavation were generally non-detectable. Metals concentrations also were generally below CCME criteria and/or were consistent with conditions in nearby sloughs.

Line 37 Fort McMurray, Alberta: *On June 22, 2013, approximately 1,300 barrels of premium synthetic crude oil were released from an Enbridge Line 37 pipeline located approximately 24.9 miles southeast of Fort McMurray, Alberta, Canada (Hemmings et al. 2015). The contaminants of concern were petroleum hydrocarbon fractions (PHC) F1 to F4, BTEX, and PAH. The oil rose to the surface in*

the saturated soils and flowed overland along the pipeline ROW to a fen and eventually reached the shores of an unnamed lake. The ROW had maintained grassy vegetation, and the fen was dominated by shrubby vegetation. The release site underwent integrated remediation (see below) that was completed in October 2013. Initial remediation efforts involved targeted excavation (soil and sediment), oil skimming of surface water, treatment of surface water and groundwater, soil flushing (fen), and installation of physical barriers (hard and soft booms). Excavation within the ROW included removing affected soil at the release site and soil beyond the release point that showed visual contamination. Depth of excavation ranged from approximately 1 to 2.5 ft below grade. Approximately 7,275 tons of contaminated soil was removed from the ROW. Remediation efforts removed a majority of the released oil (approximately 93%), and natural attenuation monitoring was employed to track the weathering and effects of the remaining product (Hemmings et al. 2015).

Soils within the ROW are generally mineral soils with a minor organic component. In the fen, peat at the surface is underlain by mineral soils of various textures (silt, clay and sand). Soil samples were collected from the ROW, the fen, and the area surrounding the unnamed lake. These samples were analyzed for BTEX, PHC F1-F4, and PAHs. Concentrations of BTEX and PHC F1-F4 were higher than acceptable Alberta Environment and Sustainable Resources, Albert Tier 1 Soil and Groundwater Remediation Guidelines in many of the samples. Following initial remediation efforts (excavation), residual oil was still detected within the soils of the ROW and fen (Hemmings et al. 2015).

A biotreatability study determined that hydrocarbon degrader bacterial populations were present in the soil in sufficient numbers to allow biodegradation to occur in the presence of oxygen or under anoxic conditions. Further study of these bacterial populations indicated that they would be capable of degrading short-chain, but less able to degrade long-chain hydrocarbons. Eco-toxicological tests were then conducted to determine if residual hydrocarbons posed a risk to ecological receptors. These tests included survival and reproduction of Collembola and avoidance-response in earthworms. Tests also were conducted to assess emergence and growth of plants. Petroleum hydrocarbons did not affect adult Collembola survival or reproduction in the ROW soils, but there was significant reduction in both survival and reproduction in the fen soils (Hemmings et al. 2015). A laboratory ecotoxicity test with earthworms was conducted and the results showed earthworms avoided the petroleum hydrocarbon contaminated ROW and fen soils and showed preferential selection for the uncontaminated reference soils. This avoidance was attributed in part to the petroleum hydrocarbons and to the low soil pH (Hemmings et al. 2015). Site-specific target levels for both PCH F2 and PCH F3 that would be protective of terrestrial ecological receptors were calculated for ROW soils and fen soils. Soil

> *petroleum hydrocarbon concentrations were generally lower than the target levels, although up to 15% of the samples from the fen had petroleum hydrocarbon concentrations that exceeded the target levels. Overall conditions at the site were considered to be "improving" one year after the release, but specific statements regarding recovery status of soils were not made and monitoring at the site was still on-going (Hemmings et al. 2015).*

To understand how soil micro-organisms are affected by oil releases and how oil can be biodegraded by soil micro-organisms, several experimental release sites have been evaluated. The results of such studies are summarized below.

In 1976, at the Caribou-Poker Creek experimental release site in Alaska, for each experimental release, about 2,000 gallons of Prudhoe Bay crude oil was released on a plot 11 by 55 yards in size. Research showed that total fungal biomass decreased and heterotrophic bacterial biomass increased in the first growing season, a trend that appeared to persist for at least a decade (Garron 2007). Lindstrom et al. (1999) found no significant differences in the total bacterial numbers between uncontaminated and hydrocarbon-affected soils, but the population diversity (evenness and/or richness) was diminished in hydrocarbon-affected soils. The hydrocarbon-affected soils did have higher numbers of more oil-tolerant species when compared to uncontaminated soils.

In a study carried out from 1970 to 1971 at Tununuk Point, located on the southern tip of Richards Island, Northern Territory, Canada, light gravity sweet crude oil was applied to plots ranging in size, topography and vegetative cover in spring, summer, and winter. Oil application rates included 0.00 cm (control), 0.25 cm, 0.40 cm, 0.50 cm, 0.75 cm and 1.5 cm in thickness to simulate releases ranging up to 1,950 barrels per acre. Gossen and Parkinson (1972) found that after approximately one year, bacterial numbers and respiration rates in oil treated samples increased, relative to untreated samples.

Sexstone and Atlas (1977) also observed increases in populations of hydrocarbon-degrading soil microbes at an experimental site at Point Barrow, Alaska. Prudhoe crude oil was applied through a perforated plate to provide even coverage at concentrations of 5 L/m^2 and 12 L/m^2, simulating moderate and heavy oil releases. During the first summer following the experimental release, microbial response was limited to the surface soil (top 0.8 in. [2 cm]), but in the following year this extended to greater depths depending on the drainage characteristics of the soil. Researchers anticipated that increased numbers of heterotrophic microbes, including oil utilizers, would persist for at least a decade after the release. Sexstone et al. (1978) also found that oil released onto tundra soils infiltrated the soil, and microbes in the saturated areas showed decreased abundance. However, around the perimeter of these saturated areas, microbial numbers were higher than those found in the reference locations. At the same experimental site, Linkins et al. (1978) found evidence indicating that the organisms were actively modifying the oil and using it to support their metabolism.

Based on these data and observations, it appears that oil releases can have a large effect on both the physical and chemical characteristics of soil. With the change in conditions, certain microbial species are negatively affected, but studies also show that the microbial community is diverse and as a whole is generally able to adapt to the presence of oil and take advantage of petroleum hydrocarbons as an energy source.

7.1.2.8.3 Expected Effects of Released Oils

Soil effects resulting from a release of crude oil from a pipeline would occur as oil is dispersed into the soil vertically and horizontally through interstitial (pore) spaces. For small releases, the oil would likely be contained within the pipeline installation trench, where soil bulk densities tend to be lower. For larger and higher rate releases, oil is expected to migrate through the soil in all directions including laterally and vertically down to the groundwater table. Because oil is less dense than water, oil migrating to the water table tends to form a floating pool, although some constituents are soluble in water and would dissolve, if present (see Section 1.3.2). In addition to lateral and downward dispersal, the oil could also mound within the pipeline trench as a result of hydraulic pressure, potentially surfacing and spreading laterally across the soil surface based on topography. Once on the surface, oil would pool in low lying areas and infiltrate into the soil subsurface, migrating laterally and vertically to the groundwater table. The degree of lateral surface migration would depend on the volume of oil that reached the surface, as well as slope, ground cover, type of oil (viscosity considerations), and temperature.

Environmental effects on soil as a result of oiling are measured by the presence and concentration of oil components such as the F1-F4 fractions, the monoaromatic BTEX compounds, PAHs, and some metals (e.g., nickel and vanadium). Oil presence may modify important soil characteristics, including but not limited to nutrient availability, porosity and water repellency, and in changes to vegetation and soil invertebrate communities. The presence of oil in soil can significantly affect plant growth (De Jong 1980), and petroleum hydrocarbons can affect survival, reproduction, and presence of soil organisms (Hemmings et al. 2015).

Soil quality standards have been developed for petroleum hydrocarbon contaminants in soil, so that after remediation, the capacity of the soil to support plants and invertebrate communities, as well as various human uses (e.g., residential, agricultural or industrial land use) should be restored. At the same time, further natural recovery can occur within a reasonable timeframe. Typically, highly contaminated soil is mechanically removed and hauled to suitable landfill, composting, or recycling facilities. Excavation and hauling will typically cease at a point when the remaining contaminated soil meets standards or guidelines typically established by federal or state agencies, or at a point when continued excavation is deemed to cause more environmental harm than good. The less contaminated soil areas would then be subject to continued monitoring during a natural attenuation process until remediation objectives can be met and the site clean-up procedures can be closed.

Like any contaminant, the potential effects resulting from the introduction of crude oil into the soil matrix depends on contaminant concentration, type of oil released, the soil receiving

environment and environmental conditions such as temperature, precipitation and snow cover. When applied as a fine spray over a large area (i.e., at low concentrations), the soil may be able to absorb the oil without deleterious changes to its physical structure. The oil droplets readily adhere to the existing organic matter and have a negligible effect on the moisture content, or porosity.

Where large volumes of oil are rapidly released onto or under the ground, the oil can fill the pore spaces between soil particles. Once the soil becomes saturated with oil, both air and water are displaced. Within these highly saturated soil zones, microbial activity can be greatly impaired both by the direct toxicity of the oil and by the altered physical and chemical condition of the soil. In contrast, a suitable environment for microbes can exist around the periphery of this saturated zone, where water and air are still present with the soil. Although this peripheral zone may be suitable for the survival and growth of microbes, the abundance and diversity of organisms may be different from pre-release conditions.

Table 7-27 and Table 7-28 provide a summary of the expected environmental effects of oil releases to soils. Table 7-27 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-28 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-27 Land Cover Receptor: Soil

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Viscosity	Low viscosity allows for greater soil infiltration and migration potential.	Medium viscosity allows for an intermediate infiltration and migration potential when compared with Light and Heavy Crude.	High viscosity and density allows for less soil infiltration and migration potential.	The viscosity of fresh diluted bitumen is lowered to meet pipeline specifications through the addition of a diluent, which may (e.g., condensate) or may not (e.g., synthetic crude oil) be volatile.
Oil chemistry—BTEX	Light crude oils often contain high levels of BTEX and other relatively water soluble hydrocarbons leading to a higher potential to cause acute toxicity to plants and soil invertebrate communities.	Medium crude oils often contain moderate levels of BTEX and other relatively water soluble hydrocarbons, leading to a moderate potential to cause acute toxicity.	Heavy crude oils often contain lower levels of BTEX and other relatively water soluble hydrocarbons, leading to a lower potential to cause acute toxicity. However, diluted bitumen products often contain similar concentrations of BTEX compounds to lighter crude oil types, due to the addition of diluent.	
Oil chemistry—TPAH	Bakken Crude has proportionally more naphthalenes and alkyl naphthalenes than Alberta oil sands products (Yang et al. 2011).	Medium weight crude oil has proportionally more naphthalenes and alkyl naphthalenes than Alberta oil sands products (Fingas 2010; Yang et al. 2011).	Diluted bitumens typically have similar to lower concentrations of TPAH than light and medium crude oils, although the distribution of PAHs differs.	Low molecular weight PAHs are usually relatively depleted in bitumen from the Alberta oil sands, due to in situ weathering.
Oil chemistry—resins and asphaltenes	Light crude oils contain little in the resins and asphaltenes fraction relative to medium and heavy crude, making their lighter aliphatic and LMW aromatic components relatively bioavailable and subject to weathering.	Medium crude oils also contain relatively small fractions of resins and asphaltenes, although more than light crude oils. Medium crude oils also have good potential for biodegradation in the environment.	Heavy crude oils, and diluted bitumens in particular, contain large amounts of resins and asphaltenes. While these fractions are generally insoluble in water and of limited toxicity, they are slow to degrade and can act as reservoirs for the slow release of other more toxic hydrocarbon constituents such as LMW and medium weight PAHs.	

Table 7-28 Land Cover Receptor: Soil

Environment Characteristic	Low	Medium	High	Other Comments
Organic carbon content	Organic carbon can bind petroleum hydrocarbon residues, lowering bioavailability. Soil with low organic carbon content (<1% of soil dry weight) will poorly sequester petroleum hydrocarbons in soil, facilitating bioavailability of these released hydrocarbons.	Soil containing a moderate amount of organic carbon (1 to 6% of soil dry weight) can help to sequester released oil.	Soils containing abundant organic carbon (>6% of soil dry weight) may be less bioavailable relative to low and medium organic content soils, due to the competing effect of soil organic carbon on bioavailability.	
Soil grain size	Fine-grained soils (clay, silt) may limit oil infiltration into the subsurface.	Medium-grained soil (fine sand to coarse sand) will allow for moderate oil infiltration.	Coarse-grained sediments (gravel, cobble) will allow for rapid oil infiltration.	
Slope	Flat and low slope areas would limit the surface spreading of oil, facilitating pooling and oil infiltration.	Oil spreading will be enhanced relative to flat land soil surfaces.	Steeply sloped areas would increase surface spreading of oil.	

7.1.3 Biological Receptors

7.1.3.1 Terrestrial Vegetation

7.1.3.1.1 Description

Terrestrial vegetation consists of the communities of plant species found on land. For the purpose of this discussion; the terrestrial vegetation resource category also includes lichens and mosses. There are over 230,000 different terrestrial plants ranging from simple forms such as horsetails, and ferns to gymnosperms (including conifers) and angiosperms (flowering plants). The terrestrial vegetation growing in a particular area and time, with specific groundwater, climatic, topographic, and soil conditions, can be grouped into plant communities. Individual plant species interact with each other through competitive, symbiotic, or mutualistic biological interactions.

Plants can be classified by their growth habit (their general appearance, growth form, or architecture (USDA 2016)). The dominant growth habits are trees, shrubs, and herbaceous plants. Trees are defined as perennial, woody plants with a single stem, normally greater than 13 to 16 ft in height (USDA 2016). Shrubs are perennial, multi-stemmed woody plants that are usually shorter than the typical height identified for trees (USDA 2016). Herbaceous plants can be annual, biennial, or perennial, but do not have significant woody tissue above or at the ground (USDA 2016).

Plant communities provide critical ecosystem functions, including soil stability, nutrient availability, nutrient fixations, water retention and cycling; as well as habitat, forage, and shelter for organisms. Plants are the first level of the food chain. They conduct photosynthesis, a process that converts light energy, water, and carbon dioxide into photosynthates (i.e., sugars, starches, carbohydrates, and proteins) and oxygen (Whiting et al. 2015). Plant roots interact with soil organisms, including mycorrhizal fungi, fungal pathogens, bacteria, and invertebrates. Together plants and the soil organism community compose the soil food web. Soil organisms are key components in the degradation of organic contaminants such as oil.

7.1.3.1.2 Observed Effects

The majority of studies on the effects of oil releases on vegetation focus on wetlands, marshes, and riparian environments. There have been limited studies specifically on the effects of crude oil releases on terrestrial vegetation, and most studies have focused on tundra and artic vegetation in Alaska, Canada, and Greenland. The results of these studies on the effects on vegetation from oil releases can be applied to other northern latitude areas such as Minnesota with similar vegetation communities with respect to oil release effects. Studies on the effects of oil on terrestrial vegetation have looked at both accidental and intentional experimental releases, with varying levels of clean-up. Based on the results of the studies, the most detrimental effect on vegetation is damage to photo-synthesizing plant tissues. Other negative effects include oil permeating the soil and affecting soil microorganisms, root uptake, and soil water availability. Oil sealing the surface soil layer, and affecting soil moisture infiltration can result in

loss of vegetation through loss of soil moisture, changes in soil temperature and nutrient availability, and reductions in growth, health, and flower bud/seed development. The extent of oiling of individual species has been demonstrated to affect the degree of plant survival (Racine 1994). When an oil release is small or there is rapid remediation of the oil, many long-term effects can be avoided.

The following discussion summarizes relevant case studies on the effects of various oil types on terrestrial vegetation.

> ***Mackenzie Delta, Northwest Territories, 1970****: Wein and Bliss (1973) reported on an experimental releases conducted in northwestern Canada east of the Mackenzie Delta. The test plots were set up in five plant communities: black spruce-alder-heath; medium shrub-alder-heath; sedge-cotton grass-heath; willow-birch-heath; and sedge. Each of the plant communities are underlain by permafrost. Results of this study are applicable to areas where a release occurs in locations with an impermeable layer, frozen soils, or winter conditions. Plot sizes varied in each plant community to account for vegetation diversity and microtopography, with the black spruce-alder-heath having the largest plot (16.4 ft x 16.4 ft [5 m x 5 m]), the willow-birch-heath having the second largest plot (13.1 ft x 13. 1 ft [4 m x 4 m]), and the remaining vegetation communities having 9.8 ft x 9.8 ft (3 m x 4 m) plots. For each plot, the researchers applied Norman Wells light-gravity-sweet crude oil in either spring, summer, or winter at one of four rates. The four rates applied to the plots included: 1) control rate (0 inch.); 2) a quarter of the highest rate; 3) half of the highest application rate; and 4) the highest rate (typically the rate required to saturate the plot). The highest rate saturated the soil profile (approximately 1,300 barrels/acre for spring/winter and 1,950 barrels/acre for summer). The active layer is the portion of the soil above permafrost that thaws and freezes seasonally. In the summer this layer is deeper, which allowed a larger amount of oil to be absorbed before runoff occurred, consequently requiring a higher rate of application in the summer to saturate the soil profile. In spring and winter, the rates of application (i.e., oil thickness on the plots) were 0 in., 0.10 inch (0.25 cm), 0.20 inch (0.5 cm), and 0.39 inch (1 cm); while in the summer, the rates were 0 inch, 0.16 inch (0.4 cm), 0.30 inch (0.75 cm), and 0.59 inch (1.5 cm). In all plots, the low lying vegetation, including low shrubs, were saturated. Different temperatures of oil (194°F and -4°F) were applied in winter to see if oil would penetrate deeper into the snow cover based on oil temperature, but no statistically significant difference was observed.*
>
> *Initial effects on vegetation for the summer treatments were observed within hours of oil application on deciduous species. The initial observations included a water soaked appearance, dry tissue, and the vegetation turning brown. Effects to evergreen shrub species took several weeks. Signs of survival or regrowth were observed within weeks for some plots and species; however the regrown leaves*

tended to be thinner and larger when they grew back than control plants. In plots where the soil was saturated with oil, the vegetation showed no evidence of recovery during the treatment year. On the winter treatments plots, there was a lack or delay in spring growth compared to untreated areas.

After one growing season, plant recovery, based on ground cover of new growth, was between 20% and 55% depending upon the treatment rate, morphological and physiological differences among species, and the season of the treatment. Most of this new growth was from latent buds of dwarf shrub species and sedges. Lichens and the majority of molds showed no regrowth. The species that showed the greatest recovery were the dwarf shrubs.

The extent of effects to vegetation damage and recovery was a combination of the amount of oil applied, and the seasonality of the treatment. In general, the treatment plots with higher rates of oil application had decreased recovery comparative to the treatment plots with lower rates of oil application. Plots where the oil was applied later in the season, and after the snowfall also had decreased rates of recovery. The amount of oil and the seasonality affected how deep and how much of the oil penetrated into the soil based on the depth of the active layer and the permeability of the soil. Greater applications of oil and the deeper active layer led to the greatest effects on vegetation.

***Norman Wells, Northwest Territories, 1972**: Fresh un-weathered Norman Wells light-gravity-sweet crude oil and Arctic diesel were used in an experimental release by the researchers on a black spruce-dominated boreal forest located south of Norman Wells, Northwest Territories along the bank of the Mackenzie River (Hutchinson and Freedman 1978). The site was observed for five years after the experimental plots were treated. Follow-up studies of the same area were conducted in the early 1980s (Hutchinson 1984).*

One treatment and one control plot (32.8 ft x 32.8 ft [10 m x 10 m plots] subdivided into 25 subplots) were set up in an early succession 30- to 40-year-old post-burn area, while two treatment plots of the same size were set up in an older mature forest community that had not experienced a forest fire in more than 80 years (Hutchinson and Freedman 1978). A summer crude oil release was simulated in both communities with oil application occurring on July 5, 1972. A winter crude-oil release was simulated in the mature forest site only with oil application occurring on March 5, 1973. A simulated summer diesel oil release was conducted only in the post-burn area with oil application occurring on June 25, 1975. For each of the experimental plots, oil was sprayed evenly over the ground surface to simulate an oil release. In addition, in the post-burn area, a single-point crude oil release was simulated by pouring approximately one barrel oil onto a fixed point in the center of a 131 ft x 131 ft (40 m x 40 m) grid.

Observations on the summer crude oil sites, noted that within several days of the release, the mosses turned black, and sedges turned brown and withered. The leaves of deciduous trees developed large brown necrotic patches where they had been sprayed with the oil. Unsprayed foliage initially remained healthy and green (Hutchinson and Freedman 1978). For all sites, there was a reduction in vegetation on treated plots that varied in length and intensity. The summer simulated crude oil release was more damaging to the vegetation than the winter release. The point-release damaged less surface area per unit of oil than when the oil was sprayed on the plots, because most of the oil in the point release was absorbed by the organic matter or percolated into the soil profile. Similar effects to vegetation were observed on the diesel oil release plot as compared to the crude oil plots.

Some species recovered within a few weeks on the winter site plots. Recovery from the summer release progressed more slowly. During the study period, recovery of existing plant species occurred predominantly through re-sprouting from surviving aboveground and below ground perennating structures (e.g., shoots, rhizomes, tubers). Some shrub and perennial vascular species developed regrowth shoots within weeks of the release, but these plants died by the following spring. Successful seed establishment was not observed for at least four years post-release. Based on the cover and frequency data collected during the study, the study authors estimated that it would take a minimum of 20 post-release growing seasons to re-establish total ground cover on the treated plots.

Researchers noted that they expected the composition of the re-established vegetation community would be different from the post-release community due to the differing capacities of species to survive and recover from a release (Hutchinson and Freedman 1978). For example, coniferous tree species recovered more slowly than shrub and ground cover vegetation. Within three to four years from the experimental treatment, mosses started to recolonize the sites. Although many of the black spruce exhibited no serious short-term effects, significant mortalities of the black spruce was observed up to four years after the release, and no regeneration of this species occurred during the six years of monitoring. Similarly, no regeneration of larch was observed and no seedlings were found during the study period.

Ten years after the initiation of this study (1980), total vegetative cover and species diversity were substantially lower compared to the control sites. In some areas, the damage to the vegetation extended past the areas directly affected by the original release. The study suggests this was due to oil spreading underground. In general, plant communities affected by released oil were set back to an early stage of ecological succession (Robson et al. 2004), and both

forest types presented lower total vegetative cover and decreased species composition than neighboring unaffected areas.

***Mount Baker, Washington, 1972**: In the winter of 1972, approximately 164 barrels of No. 2 diesel fuel oil leaked out of storage tanks at the Cascade Field Station near Mount Baker, Washington. The owner of the research station was not identified. The oil inundated two subalpine meadow communities: one heather meadow and one sedge meadow. The recovery of these plant communities was studied over the following nine years (Belsky 1975; Belsky 1982). Within two growing seasons, the released oil reduced vegetative cover from 100% to 1% and killed all, but three plant species: a heather (Phyllodoce empetriformis), a sedge (Carex lenticularis), and a moss (Rhacomitrium sudeticum) (Belsky 1982). By the second growing season after the release, seedlings of Carex nigricans, a species of sedge, appeared in the wetter areas, and seedlings of other subalpine species reappeared over the next four growing seasons. After nine years, 5 to 20% of the area affected by the release was covered by seedlings, and 20% of the heather community and 10–20% of the sedge community was covered with vegetation.*

Belsky (1982) stated that the effect of the release on the meadow communities was reduced by the snow cover, steep terrain and snowmelt. Much of the oil flowed down the steep slope rather than pooling and becoming stranded, and summer snow melt helped flush much of the oil out of the area reducing the potential exposure of emerging vegetation. In addition, the timing of the release may have reduced impacts on these communities. Plants were dormant at the time of the release and the frozen ground likely helped protect underground roots. Although diesel fuel is initially more toxic to plants (Walker et al. 1978, Wein and Bliss 1973), it is comprised of relatively small chain, highly refined hydrocarbons, which tend to weather more rapidly relative to heavier oils with a higher proportion of high molecular weight PHCs. By the time plants began to emerge, the remaining oil was less toxic to the plants than it would have been at the time of the release.

***Moose Jaw, Saskatchewan, 1974**: In the winter of 1974, a pipe carrying asphalt-based oil (23 API gravity) broke north of Moose Jaw, Saskatchewan. The responsible party for the release was not identified. Approximately 15,725 barrels of oil were released. Although two-thirds of the oil was recovered from excavated trenches during the emergency response effort, an estimated 39.5 acres (159,850.83 m^2) of agricultural land was oiled. Remediation of the affected area was not conducted. Beginning in the spring of 1974, grain crops (barley, oats and wheat) were planted to study their performance as a tool for delineating the contaminated areas. Fertilizer, limited to the maximum rate tolerated by the crops, was applied to enhance the rate of oil degradation. In 1974, the results indicated that oil content over one percent (10,000 mg/kg) was associated with*

zero growth. Crop yields on the contaminated areas improved from 1975 to 1978, but were still lower than for uncontaminated areas. In 1978 total yield of wheat from the contaminated sites ranged from 620–8,010 lbs./ac (695–8,990 kg/ha) as compared to the uncontaminated areas with a total yield of 5,550 ± 1,220 lb./ac (6,230 ± 1,370 kg/ha) (De Jong 1980). Oil content and yield were negatively correlated, but there was considerable variability in the data, which was attributed, in part, to the non-uniform distribution of oil in the root zone.

***Caribou-Poker Creek, Alaska, 1976**: In a test release at the Caribou-Poker Creeks Research Watershed, approximately 48 barrels of hot Prudhoe Bay heavy crude oil (27.5 API gravity) were applied to two 0.12 acre (500 m^2) plots in an open black spruce forest. The test release was conducted by scientists with the Cold Regions Research and Engineering Laboratory (Garron 2007). One experimental release occurred in the winter (February 1976) and the other in the summer (July 1976). The oil was released through a 16 ft (5 m) wide perforated pipe located at the top of the test plots and allowed to flow downslope (Collins et al. 1994). Oil from the winter release primarily flowed under the snow and over the frozen ground and did not go below the surface until the ground thawed. By 1978, the total area covered by the winter release was approximately 807 ft^2 (75 m^2) and approximately 40% of the release area had surface oil visible (Collins et al 1994). In contrast, the soil from the summer release flowed primarily into the organic layer before spreading downslope. The summer release covered an area of approximately 3,261 ft^2 (303 m^2) and only about 10 % of that area had visible surface oil. After three years, nearly all vegetation had died in areas where oil flowed over the surface, but effects from the release were delayed where the oil was below ground and there was less vegetation mortality in these areas (Collins et al. 1994).*

The releases were conducted in open black spruce (Picea mariana) forests with a shrub understory of resin birch (Betula glandulosa), Labrador tea (Ledum decumbens), blueberry (Vacccinium uliginosum) and willow (Salix sp.). Ground cover was primarily mosses and lichens with scattered cotton grass (Eriophorum vaginatum) tussocks. Most mosses, lichens and shrubs died shortly after the initial release, but the cotton grass persisted. Based on surveys 15 years after the releases, the cotton grass appeared to have thrived following the releases (Collins et al. 1994). The response of the cotton grass was attributed to less competition from other species. The black spruce tree also experienced mortality. Surveys conducted 15 years after the releases, determined that approximately 56% of the black spruce trees on the winter plot were dead and about 38% of the black spruce trees were dead on the summer plot. No black spruce seedlings were observed in either plot, although the remaining trees were bearing cones (Collins et al. 1994). The winter oil release produce more oiled surface area and

thus had more long-term and chronic effects on the plant communities (Collins et al. 1994).

***Bemidji, Minnesota, 1979**: At this site, a Lakehead Co. pipeline released approximately 10,700 barrels of light, low-sulfur crude oil in August, 1979 (Nieber 2013, Associated Press 2014a). The oil sprayed over approximately 1.6 acres (6,500 m²) and collected in topographic depressions before infiltrating the soil into the groundwater. Clean-up efforts resulted in the capture and recovery of approximately 80% of the released oil. Following clean-up of the areas with pooled oil, the oil-sprayed vegetation was burned. The area has remained relatively devoid of vegetation for most of the last 30 years due in part to the water repellent nature of the surface soil as a result of the burning. Vegetation (species not identified) now is primarily found in topographic depressions where run-off provides sufficient water to support growth (Nieber 2013). Further inhibiting re-vegetation has been erosion of the exposed de-vegetated soil down to the rocky substrate. For this release, the delayed recovery was predominately the result of clean-up efforts (Nieber 2013).*

***Mesters Vig, Northeast Greenland, 1982**: An experimental study was conducted in northeast Greenland on the effects of North Sea (light sweet) crude and diesel oils on wet marsh, grassland, and three types of dwarf-shrub heath (Holt 1987). Plots of 10.7 ft² (1 m²) were set up in the five plant communities. In August 1982, researchers applied North Sea crude oil and diesel oil to separate plots within each of the five plant communities. To approximate a spray release, 0.06 barrels of oil was applied to each plot at an even coating of approximately 0.4 in. Monitoring of effects was conducted for the following three years after application; however, vegetative damage was evident in the first week after the oils were applied. On the crude oil plots, the leaves lost chlorophyll turning yellow or brown; on the diesel oil plots, the leaves lost chlorophyll or were shed. After three years, the total vegetative cover in each of the five plots treated with crude oil was less than prior to application treatment, with the driest sites that began with the least vegetative cover showing the least amount of recovery. The total plant cover in the sparse dry dwarf-shrub heath decreased from 40% prior to treatment to only 0.6% by the third growing season after the treatment (Holt 1987). In comparison, the total plant cover in the wet graminoid marsh decreased from 126% prior to treatment to 23% post-treatment. In addition to the decrease in cover was a reduction in species diversity. The species diversity in each post-treatment community was less than 50% when compared to the pre-treatment communities (Holt 1987). Based on percent cover after three growing seasons, the shrubs and mosses in the communities treated with crude oil showed the best recovery whereas the graminoids (grass and grass-like plants) and forbs showed very limited recovery.*

The plots treated with diesel oil also showed reductions in total cover with the drier sites experiencing the least amount of recovery. The recovery of vegetation was more limited in the diesel treated plots than the crude oil plots. Regardless of the community, shrubs and forbs showed almost no recovery after 3 growing seasons; graminoids and mosses showed some recovery, but recovery was very limited in the drier communities (Holt 1987). In both treatment groups, the wet or mesic conditions appeared to reduce the effects of the oils, which may have led to better recovery. In these wetter sites, the water may have helped protect the belowground structures (i.e., roots and rhizomes) from the oil. The toxic effects of the diesel oil were more significant and the diesel treated plots showed little or no recovery except for mosses and three species of sedge (Holt 1987).

***Tulita (Fort Norman), Northwest Territories, 1988**: Seburn et al. (1996) experimented with a crude oil release designed to simulate a small-scale subsurface pipeline rupture. The study was conducted at the Studies of the Environmental Effects of Disturbances in the Subarctic project site. The study looked at an experimental subsurface point release of approximately 21 barrels of Norman Wells light-gravity-sweet crude oil on a simulated ROW and a simulated buried pipeline trench. The ROW was cleared of trees and shrubs, but the surface vegetation and organic layer were left intact. For the simulated buried pipeline trench, essentially all of the vegetation (trees, shrubs, low-growing plants, mosses and lichens) was removed as was the surface organic soil layers (Seburn et al. 1996). The simulated pipeline trench was fertilized and seeded with an agronomic seed mix. For the study, oil was pumped into an open ended pipe that was buried about 3.3 ft deep, where it flowed to the surface covering approximately 0.17 acres. Sampling was conducted using 9.8 in x 9.8 inches (25 cm x 25 cm) quadrats located in the cleared ROW and simulated trench. After treatment, sample quadrats were classified as heavy, medium or lightly oiled, based on the amount of visible oil in each quadrat.*

The mean total plant cover in the heavily oil ROW declined from almost 75% prior the release to less than 20% a year after the release. Both the lightly oiled ROW and the unoiled ROW showed no significant changes in mean total plant cover the year after the release, but cover increased significantly in the following two years (Seburn et al. 1996). For the simulated pipeline trench, neither the heavily oiled nor lightly oiled areas showed significant changes in mean total plant cover the year after the release. By two years after the release the mean total plant cover in both the heavily and lightly oiled areas had increased significantly above pre-release levels (Seburn et al. 1996). The simulated pipeline trench had standing and flowing water on the surface that kept the soils saturated and limited how much oil could penetration into the soil, which in turn reduced the effects of the oil on the vegetation community. In addition, the soils within the

simulated pipeline trench lacked the organic soil component present in the ROW soils, which absorbed and retained the oil (Seburn et al. 1996).

In the heavily oiled ROW, cover of 16 of the total 30 plant taxa changed significantly after the release with some of these taxa completely eliminated from the study quadrants (Seburn et al. 1996). Two of the 16 taxa increased post-release. By the third year post-release, both the agronomic grasses and cotton grasses had increased significantly above pre-release levels. In the lightly oiled ROW and both the lightly and heavily oiled simulated pipeline trench, 6 or fewer taxa changed significantly after the release. A few species appeared to tolerate the oil. Except in the heavily oiled ROW, the cover of mosses increased significantly by the second or third growing season. Researches attributed the increase in mosses to the physiological adaptation where by most of these taxa do not draw water from the soil (Seburn et al. 1996). Other taxa, sedges and cotton grasses, also appeared to experience limited effects from the oil and in many situations experienced significant increases in cover. Because cotton grasses establish new root systems each year, researchers suggested that this adaptation might reduce the effects of oil that penetrates into the soil. The researchers noted that identifying effects from the oil were complicated by the clearing and trenching activities, but they attributed the more persistent changes in vegetation to the oil (Seburn et al. 1996).

***Fort McMurray Alberta, 2013**: In 2013, an Enbridge pipeline running south from Fort McMurray in northern Alberta released approximately 1,300 barrels of premium synthetic crude oil (Hemmings et al. 2015). The release occurred underground, but the oil migrated off the pipeline right-of-way into a neighboring forested area and fen. Contaminants of concern included PHC, BTEX, and PAH. An emergency response and release recovery was initiated immediately, which included remediation of soil, groundwater, and fen material. The remediation removed 93% of the oil. Remedial activities consisted of excavating visibly effected soils, sediments, and vegetation; flushing of the fen; and oil recovery from an adjacent lake. Due to the rapid response combined with natural volatilization and degradation, effects to plants, beyond the effect of the remediation operation itself, were not initially observed. However, during the on-going monitoring program the following year, stressed and dead birches were observed (Hemmings et al. 2015). An ecotoxicological assessment was completed to determine if the remaining hydrocarbons posed a risk to vegetation and other ecological receptors. The assessment used sediment and soils that remained in place after initial remediation efforts. Negative effects to shoot and root lengths for bluejoint reedgrass (Calamagrostis canadensis), and to shoot length for black spruce (Picea mariana) were observed.*

7.1.3.1.3 Expected Effects of Released Oils

The literature review on the effects of oil releases on terrestrial vegetation provides detail on what factors will play a role in determining the severity of effects. The identification of these factors is limited since the majority of the studies were conducted in northern latitudes for similar plant communities. The majority of the releases studied occurred over 30 to 40 years ago, and as such, may not reflect current clean-up methodologies.

In general, direct exposure of plants to the oil types as described in the above case studies results in direct damage to active living tissue or killing of the entire plant. The temporal extent of effects and recovery of vegetation can be a function of oil type, the mechanism of release (spray, point, or subsurface), the seasonal timing of the release, the oiling intensity, and the method of clean-up. Long-term effects to vegetation result from changes in soil moisture and nutrient availability, oil saturation in the soil reaching the roots, and changes in plant communities based on the immediate direct effects.

Holt (1987) and Hutchinson and Freedman (1978) compared the effects of diesel oil to crude oil on vegetation. Other studies evaluated one type of oil typically at various rates of application or different seasonal timing of the release. Holt found greater effects to vegetation from the initial application of diesel oil compared to crude oil. In contrast, Hutchinson and Freedman (1978), observed similar effects to vegetation from diesel oil and crude oil. The effects of a diesel oil release on subalpine meadow communities at Mt. Baker may have been limited because the release occurred during the winter and the oil had an opportunity to weather before plant emergence and because the steep topography and snow melt that helped oil flush oil from the area (Belsky 1975, 1982). None of the studies made any observation or provided any analysis in terms of effects being greater for different types of crude oils (e.g. light, medium, heavy).

The method of a release, the timing of the release (summer vs. winter), the species exposed , and the amount of oil released all combine together as factors that influence how much of the active living plant tissue is directly affected by the oil, how much of the oil penetrates to the roots, and the surface area affected. Spraying the oil on the vegetation to provide an even coating appeared to have the greatest damage to vegetation. For most of the studies, the application of oil in the summer had a greater long-term effect on vegetation recovery. Frozen or saturated soils can minimize the penetration of oils into the soil profile, allowing time for evaporation of the oil, and for spring run-off events to transport it away from the release area. The timing of the release in relation to the life stages (e.g., sprout, seedling, mature) or annual cycles of the individual plants (e.g. seeding, flowering) can affect the sensitivity of the plant, and its correspondent reproductive functions such as flowering and seed production, to released oil. For example, releases that occur before or during flowering, especially for annuals, could result in decreased seed production, and substantially decrease future vegetative cover for those species.

Vegetation communities that were lightly oiled generally experienced less change in cover and composition when compared to heavily oiled communities (Seburn et al. 1996). Effects also varied due to growth form, species morphology and physiology. For ground-level releases, trees may not show noticeable effects from the oil for months to years after the release and only if sufficient amounts of oil penetrate the soil and affected their root system. Once the root systems are affected, it can take many years for the tree component of a community to recover (Collins et al. 1994). Groundcover vegetation such as graminoids, forbs and mosses typically experience significant declines almost immediately after a release, although some species including cotton grasses and some sedge survive and increase in cover within a relatively brief period (Collins et al. 1994; Seburn et al. 1996). Vegetation that better tolerates oil releases and recovers more quickly appears to have adaptations such as annual growth of new root systems that may promote their recovery.

In most of the case studies, over time vegetation was able to recolonize disturbed areas without clean-up efforts, however, post-release vegetation typically had lower percent cover, often with shifts of dominant species and habit. New growth typically developed from root stock or rhizomes of perennial species, existing seedbanks in undisturbed soils, and unaffected vegetation that spread from undisturbed areas into disturbed areas. Recovery was dependent on soil types, vegetation community types, morphological characteristics of individual species, spring runoff, and the infiltration depth of the oil. Even though vegetative cover may recover, oil may remain present in the area. In areas where oil was not removed from the soil, vegetation typically did not recover, or only species that appeared to be oil tolerant revegetated the disturbed areas. The time to recovery is highly variable and is dependent upon both the characteristics of the release and the characteristics of the affected plant community.

7.1.3.1.4 Summary of Inland Oil Release Effects on Terrestrial Vegetation

Table 7-29 and Table 7-30 provide a summary of the expected environmental effects of oil releases to terrestrial vegetation. Table 7-29 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-30 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-29 Biological Receptor: Terrestrial Vegetation

Oil Characteristic	Low	Medium	High	Other Comments
Viscosity	Oil with low viscosity would spread more slowly and have a limited effects area which would limit effects on terrestrial vegetation.	Oil with a medium viscosity would spread at a moderate rate and have a wider effect area compared to low viscosity oil. Medium viscosity oil would have a wider area of effects than a lower viscosity oil.	Oil with a high viscosity would spread at a faster rate and could have a relatively large effects area compared to low and medium viscosity oil.	The spatial extent of oiling from overland flow would be highly dependent on the local topography.
Pour point temperature	At a temperature below pour point, oil flow from a release would be minimal, limiting effects to vegetation near the oil release site.	At a temperature at pour point, oil flow from a release would be increased, effects to vegetation would be near the oil release site and spread further out from there.	At a temperature above pour point, oil flow from a release would be greatly increased, effects to vegetation would be near the oil release site and could spread a much further distance.	
Oil release volume	Lightly oiled sites are often able to recover quickly.	Sites with increased oil volume from a release have greater effects on vegetative tissue.	Sites with high volumes typically have greater effects and increased loss of species, and vegetative cover.	The volume of oil and mechanism of release are the greatest contributing factors affecting the spatial extent of oiling.
Physical and chemical properties of the oil	Lighter refined products such as diesel fuel) while initially more toxic to plants, weathers more rapidly resulting in decreased long-term effects.		Those crude oils that are more persistent take longer to weather, stay in the ecosystem and can result in longer-term effects and recovery such as decreases in plant diversity and abundance.	Selection of remedial methods to remove oil can have a significant effect on recovery.

Table 7-30 Biological Receptor: Terrestrial Vegetation

Environment Characteristic	Low	Medium	High	Other Comments
Seasonality of release	Winter: frozen conditions can limit the penetration of oils into the soil. The amount of aboveground active living tissue in the winter is also decreased, limiting effects from oil that sprays onto vegetation.	Spring/Fall: Oil not volatilized or cleaned up can move during spring melt then seep into the soil.	Summer: In general, summer releases have the greatest effects due to the deeper active soil layer and the increased active living tissue present. Releases that occurred before seeds were produced had greater effects on the next growing season's recovery.	
Soil permeability/ moisture	Soils with low permeability include those with high moisture content, high percentage of clay, or frozen soils. These soils limit the ability of the oil to penetrate and saturate the soil limiting damaging effects on the oil on the roots, nutrient content, and soil microorganisms.	Soils with medium permeability would result in increased toxicity to terrestrial vegetation due to increased saturation of the soil by the released oil. Soil saturation with oil could also go deeper in the soil profile affecting deeper-rooted plant species.	Soils with high permeability would result in increased toxicity to terrestrial vegetation due to increased saturation of the soil by the released oil. This could result in long-term effects such as loss of deep-rooted woody vegetation, and long-term decreases in total vegetative cover and species diversity.	Mosses are sometimes able to recover quickly as they lack roots in the soil and are able to stay above the oil saturated soil.
Plant habit/ type	Herbaceous (including lichen and mosses): Effects depend on timing of the release which impacts seed production. Annual species that are unable to produce seed due to a release are frequently lost from the site. Perennial species are often able to re-sprout from below ground biomass. Lichens are often permanently affected, while mosses varied in their effects.	Shrub/sub-shrub: Surface saturation can affect the actively living tissue; however shrubs are able to recover from below ground biomass (root structure) when oil contaminants stay on the soil surface. When soils are saturated and the oil reaches the roots, effects can be long-term.	Tree: When soils are saturated with oil, long-term effects, including mortality and loss of resilience may occur. Effects to trees often take several years to be observed. Oil releases that stay on the soil surface often do not affect the taller tree species.

				reclamation purposes due to their ability to survive and thrive in oiled environments.

7.1.3.2 Benthos

7.1.3.2.1 Description

Benthic macro-invertebrates (or more generally, aquatic invertebrates) are those invertebrates that live on or in the bottom sediments, including a wide variety of arthropods (e.g., aquatic insects, crustaceans, and others), mollusks, annelids, turbellarians, and other phyla. Functionally they are considered to be those invertebrates that live on or in the sediments and are visible to the naked eye or retained on a sieve having a mesh size of about 0.02 inches (0.5 mm, Barbour et al. 1999; Klemm et al. 1990). Sediments also support a wide variety of other, smaller, animal life forms.

Aquatic invertebrates are assessed here because of their ubiquitous importance in the aquatic food web (e.g., as processors of detritus and plant materials, and as prey items for fish), and for their value as bio-indicators and a monitoring tool for assessing the environmental effects of changes in water and sediment conditions (Barbour et al. 1999). Freshwater benthic macro-invertebrates inhabit a variety of substrates, ranging from soft sediments to large rocks, submerged woody debris, aquatic vegetation, and root masses (Klemm et al. 1990).

Because benthic macro-invertebrates are abundant in most waterbodies, relatively easy to sample and identify, tend to stay in a localized area, and have a wide range of feeding strategies and tolerance of environmental conditions, they are a common tool for monitoring health of aquatic ecosystems (Barbour et al. 1999). The use of standard sampling protocols, often based on the USEPA Rapid Bioassessment Protocols for Use in Streams and Wadeable Rivers (Barbour et al. 1999), provides a consistent monitoring approach and allows statistical treatment of the data, to reliably identify adverse effects of human activities and trends over time. After identifying and counting the organisms, the data can be evaluated for abundance, diversity, evenness, species composition, dominance, and other community indices that indicate environmental disturbance, relative tolerance of the organisms present, and effects of contaminants on community structure and composition (Pontasch and Brusven 1988).

In watercourses, particular attention is paid to abundance and diversity of some orders of insect larvae in riffle habitat. Ephemeroptera (mayflies), Plecoptera (stoneflies), and Trichoptera (caddisflies), referred to as EPT taxa, are considered pollution sensitive, and are abundant in conditions preferred by trout and other salmonids (i.e., undisturbed rivers and streams in riffle and run areas, with high oxygen levels, and with low levels of sedimentation, organic contaminants, and nutrient enrichment). While some EPT taxa also inhabit depositional areas of lakes, rivers, and streams, other taxonomic groups (e.g., aquatic worms, midge larvae, mollusks, and crustaceans) that naturally tolerate fine sediment are usually predominant in these areas.

The effects assessment for benthic macro-invertebrates focuses on direct effects of crude oil on invertebrate communities. Oil released to water mainly remains on the surface, but it can also enter the water column (dissolved, dispersed, or as fine droplets) or be stranded on the shore and sediment. Toxicity to aquatic biota varies with the type of oil and manner of exposure, and

can be identified through water and sediment monitoring and toxicity testing. Relevant hydrocarbon monitoring parameters are BTEX (which have low molecular weight fractions that weather quickly), PAHs (which have persistent higher molecular weight fractions), and alkanes (aliphatic hydrocarbons, straight chain with varying numbers of carbon atoms). Acute toxicity is generally associated with the lower molecular weight compounds (e.g., BTEX), some PAHs such as naphthalene, and short chain alkanes (NRC 2005).

7.1.3.2.2 Observed Effects

There is potential for crude oil released accidentally from a pipeline to reach one of the many lakes, streams, or rivers in Minnesota. Oil has the potential to affect macro-invertebrates directly through acute or chronic toxicity or smothering of habitat, and indirectly by altering essential habitat characteristics). Immediately following a release, biota can be exposed to acutely toxic hydrocarbon concentrations dissolved in the water (Stalfort 1999; Poulton et al. 1997). The low molecular weight compounds (BTEX, some PAHS, and short chain alkanes) most associated with acute toxicity generally weather and disperse quickly (NRC 2003), so that concentrations in surface water are usually below levels associated with acute effects to benthic macro-invertebrates or fish within days or weeks. Oil deposited in sediment (whether stranded along shorelines, or sunken) contains PAHs that weather and degrade more slowly than the low molecular weight compounds, sometimes over a period of years, and can be associated with chronic toxicity. Indirect effects on macro-invertebrates can occur through effects on other aspects of the habitat (e.g., increase in nutrient release from sediment, increase in algal production, decrease in dissolved oxygen levels during decomposition of the oil, and decrease in decomposition of natural sources of organic matter (Crunkilton and Duchrow 1990). Over time, and as the released oil becomes increasingly weathered, biodegraded and/or dispersed, benthic macro-invertebrate communities recover. Recovery is facilitated by natural dispersal mechanisms of these organisms, such as downstream drift, and upstream movement of aerial life stages prior to egg deposition. Remediation activities can speed up the recovery process, but the habitat-associated disturbance (e.g., removal of riparian and in-water vegetation, substrate disturbance, and flow alteration) can also result in adverse effects on the benthic community.

Observed effects of released oil on benthic macro-invertebrates are compiled from seven case studies where oil was accidentally released in freshwater environments. Only one of the case studies is for a lake, reflecting the paucity of literature available on effects of oil releases in lakes and ponds, as compared to releases into rivers and streams.

> ***Asher Creek, Missouri:*** *In August 1979, a pipeline burst, releasing approximately 9,500 barrels of an unspecified type of domestic crude oil into Asher Creek, in southwest Missouri, during low-flow conditions (Crunkilton and Duchrow 1990). A responsible party has not been identified for this incident. Dissolved oxygen, pH, and conductivity levels in water were not changed by the release (no information about hydrocarbons in water was published), and oil that entered substrates in riffle areas due to mixing was observed for over a year post-release*

(Crunkilton and Duchrow 1990). The creek originates in springs 0.4 miles upstream of the release site. Low water volumes in these headwaters, particularly during summer, provided limited dilution of the oil, increasing the residence time of soluble oil components in sediment (Crunkilton and Duchrow 1990). Areas located downstream from surface skimming siphon dams were less severely affected and recovered more rapidly than areas closer to the release, where the substrate became inundated with oil (Crunkilton and Duchrow 1990).

Recovery of the benthic invertebrate community was studied between 1 and 18 months post-release (Crunkilton and Duchrow 1990), with a focus on riffle-dwelling organisms indicative of good water quality (e.g., Ephemeroptera and Plecoptera). Sampling sites were established 0.4 miles upstream (reference area) and about 1.2, 2.5, and 5.0 miles downstream of the release location. Following an initial reduction in benthic populations to 0.1% of expected density, a decrease in species diversity, and a complete loss of some mayflies and stoneflies, the community began recovering through re-colonization from upstream areas. At nine months post-release, density, diversity, and number of mayfly and stonefly taxa had recovered to levels found in the upstream reference area, but remained below the minimum values established for unpolluted Missouri streams. At 12 months post-release, a drought during August and September resulted in a decline in these metrics. At 18 months post-release, density, diversity, and number of mayfly and stonefly taxa had rebounded and were similar to values reported for unpolluted Missouri streams. Factors slowing recovery time included the additional stress of warm summer temperatures and low flows, the large volume of the release compared to the water volume of the creek at the time of the release, and the limited area upstream for providing organisms for re-colonization (the creek originates from a spring only 0.4 miles upstream of the release site).

Gasconade River, Missouri: *On December 24, 1988, a ruptured pipeline owned by Shell Oil Pipeline Corporation released approximately 20,800 barrels of intermediate sweet crude oil near Vienna, Missouri, into Shoal Creek, a tributary of the Gasconade River. Concentrations of petroleum hydrocarbons in sediment decreased rapidly in erosional areas in the months following the release, but persisted in depositional areas (Poulton et al. 1997).*

Benthic invertebrate communities in riffle and backwater areas of the Gasconade River were sampled after the release, from March 1989 to June 1990 (Poulton et al. 1997). In affected riffle habitats, total number of organisms, taxa richness, number of EPT taxa, and EPT/Chironomidae ratio recovered to levels reported in reference areas in the first summer post-release. In backwater areas, however, benthic diversity and abundance of the macro-invertebrate scrapers and shredders functional feeding groups remained diminished until the end of the

study (18 months post-release). This continued effect was attributed to residual hydrocarbon contamination in backwater slough areas despite the ongoing decline in hydrocarbon levels in sediment over that period. Although high flows and scouring increase recovery in both riffle and backwater habitats, the increased flushing potential of riffle areas likely allowed for increased weathering and flushing of oil residue, which allowed more rapid colonization of benthic invertebrate communities in the riffle habitats compared to backwater areas (Poulton et al. 1997).

Chariton River, Missouri: *On November 5, 1990, a rupture in an Amoco Oil Pipeline Corporation pipeline released approximately 2,600 barrels of light crude oil into a small tributary that flowed into the Chariton River near Ethel, Missouri. Sediment collected from depositional areas located downstream about six weeks after the release was still found to be toxic to mayflies in laboratory experiments (Poulton et al. 1998; Ort et al. 1995).*

Benthic invertebrate surveys, using artificial substrates consisting of packs of natural leaf litter, were conducted one month and one year post-release (Poulton et al. 1998). One month post-release, there were statistically significant differences between reference and affected sites in abundance and taxon richness of macro-invertebrate collector and shredder functional feeding groups, and in EPT taxon richness. One year later, differences between affected and reference sites were no longer significant for many of the metrics, except for taxon richness and overall abundance, which remained slightly lower in affected areas. The authors stated that effects observed after the release appeared to be associated with oil absorption and substrate coating, creating conditions unsuitable for successful colonization.

Cayuga Inlet, New York: *On November 3, 1997, a Conrail train derailed and released 167 barrels of diesel fuel into a first-order reach of the Cayuga Inlet, which flows into Cayuga Lake near West Danby, New York. Diesel fuel slicks escaped the containment booms and were observed on the surface of Cayuga Lake 9.6 miles downstream of the release site within twenty-four hours (Lytle and Peckarsky 2001).*

Recovery of the benthic invertebrate community was measured four times over a 15 month period at sites 0.4, 3.0 and 7.0 miles downstream of the release, and at corresponding reference sites (Lytle and Peckarsky 2001). Immediately after the release, there were statistically significant differences for taxon richness and predominant taxa at the first two sites downstream, and for density at all three sites. Short-term effects included a 90% reduction in invertebrate density at sites 0.4 and 3.0 miles downstream, and a 50% reduction in taxon richness at the site 0.4 miles downstream. The benthic community at the site 0.4 miles downstream

was dominated in autumn 1997 and spring 1998 by a riffle beetle, of the genus Optioservus, known to tolerate oil pollution. The beetle was replaced in dominance by one highly predominant mayfly species later in 1998. At the other sites, various species of mayflies were predominant. Despite the initial severity of the effect, invertebrate density and taxonomic richness at the site closest to the release recovered within a year, with re-colonization from unaffected areas. However, the authors concluded that 15 months was not long enough for complete recovery of the benthic community at the site located closest to the release, given ongoing over-representation of a single predominant taxon at this site during the study period.

***Pine River, British Columbia**: On August 1, 2000, a Pembina Pipeline Corporation pipeline ruptured and released approximately 6,200 barrels of sour light crude oil, of which approximately 2,800 barrels entered the Pine River in British Columbia (BC MOE 2000a). The Pine River is a low gradient but fast flowing river, and oil was dispersed up to 50 miles downstream. The fast flowing water allowed rapid dispersion of acutely toxic fractions of the oil into the river water. Oil was stranded and settled in depositional areas along the banks, in back eddies and other slow-flowing areas, and on organic debris and logjams (AMEC 2001 in Lee et al. 2015). Heavy rainfall later in August and September mobilized stranded oil, oil-contaminated debris, and sediments downstream, and high water levels scoured some of the more heavily oiled depositional areas. Oil was recovered from the river over a period of two months, with about 91% of the released oil being either recovered, or accounted for through volatilization (Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015). Some of the emergency response activities (e.g., removal of logjams and woody debris, altering of backchannels, bank armoring, and presence of heavy machinery in the river) also resulted in habitat damage (Summers 2004 in Bustard and Miles 2011). Prior to the August 2000 release, a small release of diesel fuel (151 barrels) and gasoline (187 barrels) from a tanker truck had occurred in August 1994 in this area of the Pine River (Goldberg 2011).*

Petroleum hydrocarbons were detected chemically, and seen and smelled in river water up to 50 miles downstream of the release, with sheen visible in back eddies and other calm areas along shorelines. Hydrocarbons accumulated in sediments and on organic debris (e.g., branches, leaves, and algae) present along the shoreline, in front of logjams, and attached to sweeper logs in these calm areas (AMEC 2001 in Lee et al. 2015). Concentrations in water decreased rapidly to below British Columbia water quality guidelines due to evaporation, dissolving in water, and natural dispersion (Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015), all of which are characteristic of light crude oil. Oil was observed to persist in some bottom substrates five years after the release (Goldberg 2006 in Bustard and Miles 2011). Analysis of semi-permeable

membrane devices deployed in the Pine River indicated that two years after the release, hydrocarbons were present in water, implying that hydrocarbons from the release were leaching out of sediment into the water column (De Pennart et al. 2004), although additional sources (e.g., road runoff, PAHs from coal deposits in the watershed) were also acknowledged.

Immediately after the release in August, total abundance of benthic macro-invertebrates declined and there were changes in community composition apparent for at least 75 miles downstream of the release (De Pennart et al. 2004). By August of 2001, relative abundance of benthic invertebrates had recovered in much of the river (De Pennart et al. 2004; Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015). Concerns were expressed about decreased food supply for fish, especially young fish during the August–November 2000 period, which was identified as a critical period leading up to overwintering (Birtwell 2008).

***Wabamun Lake, Alberta**: On August 3, 2005, a Canadian National Railway Company train derailed and released approximately 4,500 barrels of Heavy Fuel Oil 7013 (a Bunker C type fuel oil with a high viscosity and an initial density of about 0.99 at lake temperature) and 550 barrels of pole treating oil. About 20% of the released heavy fuel oil (950 barrels) travelled overland and entered Wabamun Lake. No appreciable volume of pole treating oil entered the lake (Hollebone et al. 2011). While travelling overland, the oil mixed with soil and organic matter; and in the lake, OPAs formed quickly, including small tar balls, larger tar "logs", submerged sheets, and large lumps (Fingas et al. 2006; Hollebone et al. 2011). The aggregates showed a variety of behaviors, including submergence, neutral buoyancy, and resurfacing (Fingas et al. 2006), with extensive tar-mat formation in some nearshore areas. In the lake, the oil floated and spread rapidly over the water surface. After a few days, strong winds and wave action dispersed the oil toward the north, east, and south shorelines, where it became entrained in macrophyte beds (Anderson 2006). Behavior of oil in the lake—rapid formation of tar balls, sinking, slow degradation due to high proportions of high molecular weight components such as resins, and its toxicity and persistence (due to high PAH levels but low BTEX levels—were related to characteristics of the heavy fuel oil, which would not be comparable to crude oils and diluted bitumen, given the high density of the fuel oil. Within four months of the release, concentrations of BTEX and PAHs were below detection in lake water (Birtwell 2008).*

Laboratory tests showed statistically significant toxicity to the benthic invertebrates Chironomus tentans and Hyalella azteca for sediments collected near the release site in the weeks following the release. Test results were challenging to interpret because test conditions were not the same for all site

and control samples. Samples with high sand content had higher mortality, possibly due to sandier habitats not being preferred by the organisms, or because of the naturally low organic content and food supply in sand (Lee et al. 2015). However, growth of both species and also the aquatic worm Lumbriculus variegatus in both high- and low-sand sediments was significantly less than in control sediments. For L. variegatus, PAH concentration in sediment was correlated with toxicity (Lee et al. 2015).

Marshall Michigan: *On June 25 and 26, 2010, Enbridge Line 6B pipeline ruptured and released approximately 20,000 barrels of heavy crude oil, of which approximately 8,200 barrels entered Talmadge Creek, a tributary to the Kalamazoo River, near Marshall, Michigan (NTSB 2012a; Enbridge 2013b). The released oil was a combination of Western Canadian Select (23%) and CLB (77%) diluted bitumens (Enbridge 2013a). The release occurred on the floodplain of Talmadge Creek, where wetlands are abundant (USFWS et al. 2015a). The Kalamazoo River is a meandering, low gradient river with diverse channel and floodplain features, extensive floodplain forests and wetlands, off-channel water bodies, and impoundments (Dollhopf et al. 2014). Oil was transported downstream in the Kalamazoo River, which was in flood at the time of the release, as far as Morrow Lake (an impoundment in the river 36.5 miles downstream).*

Oil was deposited on river shoreline, riparian, and depositional areas (backwaters, side channels, oxbows) of the Kalamazoo River, and in deltaic sediments of Morrow Lake (USFWS et al. 2015a), affecting approximately 40 miles of river (80 miles of shoreline and adjacent lands) (Dollhopf and Durno 2011). There was associated disturbance from remediation efforts such as removal of riparian vegetation and sediment and access road construction (Dollhopf and Durno 2011). Some of the oil mixed with soil and organic matter while moving overland, and with suspended sediment in the water column after entering the river, resulting in formation of OPAs that submerged in some locations, especially depositional areas. These aggregates periodically released oil globules and sheen as late as 2014 (Fitzpatrick et al. 2015). Formation of OPAs was likely promoted by the flood conditions. Based on measurements of suspended sediment at the Marshall stream gage after the release, it can be inferred that the river had relatively low suspended sediment concentrations at the time of the release, but that the floodwaters likely increased the turbulence and the presence of suspended particulate matter (Fitzpatrick et al. 2015). In addition, the high organic matter content of the suspended and bottom sediments (20% or more) due to the abundant wetlands along the Kalamazoo River contributed to OPA formation (Fitzpatrick et al. 2015). Some of the submerged oil settled in areas that became anaerobic, which would reduce the rate of biodegradation.

About 90% of the oil entering the river was recovered in the first year. This included floating oil, stranded oil in the floodplains of Talmadge Creek and the Kalamazoo River, and submerged oil (Fitzpatrick et al. 2015). Much of the diluent portion volatilized, which resulted in increased density of the residual weathered diluted bitumen. In 2011, additional activities to dislodge and disperse submerged oil resulted in a small amount of additional recovery. Submerged OPAs continued to release oil from sediments in the Kalamazoo River and impoundment areas between 2011 and 2014, with surface sheens observed in impounded sections of the river (Fitzpatrick et al. 2015).

Standardized surveys and other studies indicated that benthic invertebrate communities in some sections of Talmadge Creek and the Kalamazoo River were adversely affected following the release (USFWS et al. 2015a). Some of the observed effects were attributed to effects of the oiling and some to the effects of the clean-up activities. Effects attributed to clean-up activities included bank destabilization resulting from vegetation removal and the potential for resulting bank erosion associated with heavy boat traffic (Winter and Haddad 2014). In addition, heavy boat traffic associated with the clean-up was identified as the caused for crushed mussel shell observed in the oil-impacted areas (Winter and Haddad 2014).

To examine impacts and subsequent recovery, the MI DEQ conducted standard macroinvertebrate surveys in September 2010 with additional surveys in 2011, 2012, 2013, and 2014. The Michigan Procedure 51 methods (similar to USEPA Rapid Bioassessment protocols) were used, and communities were ranked as excellent, acceptable, or poor on the basis on nine community metrics. Following the 2010 survey MI DEQ found that both abundance and diversity of macroinvertebrates were impacted due to the spill and associated clean-up activities (Walterhouse 2011). Post-2010 survey data showed improvement in both the Kalamazoo River sites and Talmadge Creek with most sites returning to near baseline conditions by 2012 (Matousek 2013; Walterhouse 2012).

Benthic macro-invertebrate communities in depositional habitat were assessed at several sites in the Kalamazoo River and in reference sites in 2012 and 2013. The 2013 results were used as part of a sediment quality triad study (along with sediment chemistry and sediment toxicity data) to evaluate effects of the release in areas known to accumulate oil (Enbridge 2014). There was high variability in community metrics among the sites, with similar trends for taxon richness, diversity, and relative abundance of Chironomidae (midge larvae) and Tubificidae (oligochaete worms) at reference and affected sites; but density (organisms per m^2) was lower at the affected sites, possibly partly attributable to higher sand content in reference site substrates compared to affected sites.

Sediment toxicity was tested in 2012 and 2013 (same depositional habitat locations as sediment chemistry) using standard laboratory tests with two species of benthic invertebrates (the amphipod Hyalella azteca and larval midge Chironomus tentans). The extent and number of samples showing toxicity decreased between 2012 and 2013 and indicated overall that toxicity was absent from most parts of the river studied (Enbridge 2014). In both years, many samples from affected areas showed no toxicity and the remainder showed low levels of toxicity (e.g., 91% survival in Hyalella and 82% survival for Chironomus) and growth reduction. However, the levels of toxicity were similar in affected and reference areas of the river, indicating a background level of sediment toxicity unrelated to the oil release (Enbridge 2014). Many samples from affected areas of the Kalamazoo River contained elevated levels of organic carbon, which were expected to reduce bioavailability of the PAHs, many of which bind to organic carbon.

The 2013 study was a sediment quality triad study, bringing together information about contaminant concentrations in sediment, sediment toxicity, and benthic invertebrate communities in depositional area. Using a weight-of-evidence approach to evaluate the ecological significance of the residual hydrocarbons in sediment, the conclusion was that release-related hydrocarbons in sediment of the Kalamazoo River were not having adverse effects on the aquatic ecosystem three years post-release (Enbridge 2014).

7.1.3.2.3 Expected Effects of Released Oils

The main effects of released oil on benthic macro-invertebrates are physical smothering of benthic habitats by oil, immediate toxicity from hydrocarbon fractions such as BTEX, and longer-term toxicity from persistent hydrocarbon fractions such as PAHs or physical contact with residual oil droplets in sediment. In addition, there may be habitat damage associated with subsequent remediation. Effects persist longer in depositional areas (pools, backwaters, or deltaic sediments where rivers deposit suspended and bedload sediments), than in erosional areas (riffles and runs of rivers and streams), where oil tends to be in transit or rapidly flushed downstream. Standard laboratory toxicity tests with oiled sediments can be used to assess acute and chronic toxicity to invertebrate species. Field assessments of benthic macro-invertebrate community structure show effects in terms of abundance and diversity of benthic organisms, and can be used to assess the health and recovery of the community. Benthic invertebrate communities recover through re-colonization of affected areas, mainly by downstream drift but also by upstream migration, movement from within the substrate, and eggs laid in the water (Williams and Hynes 1976). Case studies conducted post-release typically indicate substantial recovery for benthic invertebrate communities in rivers and streams within one year, and full recovery within two or three years. Delayed recovery may be expected in depositional areas where oil deposition is heavy, if such oil is left in place.

The effects of oil releases on benthic macroinvertebrates vary depending on characteristics of the released oil and environmental conditions at the time of the release. Relevant oil characteristics related to potential for toxicity include solubility and BTEX concentration, total PAH concentrations, resin and asphaltene concentrations, and density and viscosity. These are discussed in Table 7-31. Environmental characteristics that influence the extent of effects on benthic invertebrates include organic carbon content and particle size of the sediment, water flows, and hyporheic flow, as discussed in Table 7-32. The toxicity of oil to benthic macroinvertebrates depends mainly on the extent of exposure to oil. In general, light oils, high in low molecular weight narcotic compounds such as BTEX, are more acutely lethal than medium and heavy oils. Heavy fuel oils with high proportions of three- to five-ringed alkylated PAHs have greater chronic toxicity than light oils, generally due to their high alkylated PAH levels (Lee et al. 2015). The low molecular weight BTEX and some PAHs weather and degrade more quickly than the higher molecular weight or higher alkylated PAHs, which can persist for long periods in anoxic sediments.

Table 7-31 Effects of Oil on Benthic Macroinvertebrates by Oil Characteristic

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Solubility	Contains a large fraction of soluble low molecular weight hydrocarbons like BTEX, leading to a higher potential for acute toxicity, particularly in the water column.	Intermediate in proportions of soluble low molecular weight hydrocarbons (e.g., BTEX) between light and heavy crude oil. There is a moderate potential for dissolved hydrocarbons to enter sediment pore water and for acute toxicity.	The fraction of soluble low molecular weight hydrocarbons depends on the oil type. Conventional heavy crude oils may have relatively low solubility. However, diluted bitumens contain diluent, which may (e.g., condensate) or may not (e.g., synthetic crude oil) contain a large component of relatively water-soluble aromatic compounds (e.g., BTEX). CLWB is an example of diluted bitumen with a relatively large component of condensate, with BTEX content similar to that of many light crude oils.	Soluble fractions (BTEX and low molecular weight PAHs can result in acute toxicity to organisms in the water column. However, oil that reaches substrates inhabited by benthic macro-invertebrates will have undergone some weathering, leading to lower levels of soluble hydrocarbons.
Concentration of total PAH	Among the light crude oils, Alberta sweet mixed blend crude oil has higher total PAH and proportionally more naphthalene and alkylated naphthalenes than heavier crude oils and bitumen (Yang et al. 2011).	Among the medium crude oils, Alaska north slope crude oil has higher TPAH, and proportionally more naphthalene and alkylated naphthalenes than heavier crude oils and bitumen (Fingas 2010; Zhou et al. 2015).	Diluted bitumens typically have concentrations of total PAH that are similar to or lower than many light, medium, and heavy conventional crude oils, although the PAH "fingerprint" varies (Zhou et al. 2015, Fingas 2010). There is no current evidence to suggest diluted bitumens are more toxic than conventional light or medium crude oils (Zhou et al. 2015). Diluted bitumens tend to have relatively more of the C3 and C4 alkylated PAHs, which may be more toxic and persistent, but these PAHs are less soluble in water and therefore less bioavailable. Heavy fuel oils often contain very high concentrations of PAHs.	Many PAHs are have very low aqueous solubility and accumulate in sediment, where benthic macro-invertebrates can be exposed. They do not degrade quickly and can result in chronic toxicity to aquatic biota. Total PAH levels vary from oil to oil, even within a weight class, but as a general rule, most crude oils contain approximately 1% total PAH by weight.
Concentration of resins and	Light crude oils contain very little resin and asphaltene. The light	Medium crude oils also contain little resin and asphaltene, although	Resins and asphaltenes comprise the "heavy" end of crude oils, and diluted bitumens are proportionally richer in these	Resins and asphaltenes are generally insoluble in water and thus not biologically

Table 7-31 Effects of Oil on Benthic Macroinvertebrates by Oil Characteristic

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
asphaltenes	oils weather quickly, resulting in less extensive and shorter-term effects on habitat of benthic macro-invertebrates.	more than light crude oils. Medium crude oils also have good potential for weathering and biodegradation in the environment.	components than light or medium crude oils. Their tendency to adhere to substrates and resist biodegradation results in potential to affect habitat of benthic macro-invertebrates in both depositional and erosional habitats.	available and nontoxic. They can adhere to surfaces and are slow to degrade (Lee et al. 2015), so can act as reservoirs for slow release of other more toxic hydrocarbon constituents such as PAHs.
Density and viscosity	Light crude oils have relatively low density and viscosity. Therefore, although they float and quickly re-surface when submerged, their low viscosity allows formation of small droplets under turbulent flow conditions. Such droplets readily interact with suspended sediments to form OPAs that may have a net density greater than that of the water.	Medium crude oils have intermediate density and viscosity. Therefore, while they readily float on water, they are somewhat more resistant to dispersion into flowing water as fine droplets than light crude oils.	Heavy crude oils have relatively high density (diluted bitumens are typically engineered to have a fresh density of 0.94 or less, similar to conventional heavy crude oil types). Diluted bitumens generally have lower viscosity than heavy conventional crude oils; however, density of diluted bitumen containing a volatile diluent will increase more rapidly than density of a conventional crude oil. The higher density of heavy crude oils suggests a greater tendency to sink; however, the higher viscosity of these oils reduces the likelihood that fine droplets will form in the water column and, therefore, reduces the likelihood of OPA formation.	Density and viscosity of any oil will increase as a result of weathering post-release. Any crude oil can be deposited to sediment, under the right conditions. Wave tank testing of light (Alberta Mixed Sweet Blend) and Cold Lake diluted bitumen crude oil types with natural river sediment showed that the light oil readily formed OPAs and sank, whereas the diluted bitumen remained floating (Zhou et al. 2015).

Table 7-32 Effects of Oil on Benthic Macroinvertebrates by Oil Characteristic

Environment Characteristic	Low	Medium	High	Other Comments
Sediment organic carbon content	Oligotrophic (nutrient-poor) lakes and watercourses tend to have low organic carbon content. Sediments with low organic carbon content may be more prone to toxic effects to benthic macro-invertebrate communities than those with higher organic carbon content, as the organic matter provides binding sites for PAHs and other hydrocarbons.	Freshwater environments, including many watercourses, typically contain moderate amounts of organic carbon, which can bind some of the hydrocarbon fractions, reducing toxicity to aquatic biota.	Sediments containing abundant organic carbon (e.g., eutrophic or nutrient rich lakes and depositional areas of watercourses) may be less prone to exhibiting toxic effects on benthic macro-invertebrates. The high organic carbon content in sediments of the Kalamazoo River was cited as a factor in the low observed toxicity of sediments following the 2010 Marshall release of diluted bitumen (Enbridge 2014).	Oil residues as well as specific classes of compounds such as PAHs can bind to naturally occurring organic matter, limiting hydrocarbon bioavailability and toxicity. Sediment and water flow characteristics are frequently correlated. Flowing water tends to have coarse-grained sediment with less organic matter. Slow-moving or standing water tends to have fine grained sediment, with more organic matter.
Sediment grain size	Fine grained sediments (silt and clay) occur in depositional areas, where oil tends to accumulate. Fine-grained sediments may resist entry of OPAs, although physical mixing may introduce oil into the sediments, where it may persist due to low oxygen levels and lack of water flow. These processes can result in greater or more prolonged effects on benthic macro-invertebrates.	Medium-grained sediments (fine to coarse sand) occur in moderate flow environments, pools in rivers and streams, and some lakes. There is some potential for oil to accumulate in these areas, and the sandy sediment may resist entry of OPAs. The higher load-bearing capacity of these sediments may facilitate recovery of oil without downward mixing and persistence, resulting in less prolonged effects on benthic macro-invertebrates.	Coarse-grained substrates (gravel, cobble) are typical of relatively high flow systems (riffle and run habitat of rivers and streams), where oil does not tend to accumulate. However, oil and OPAs can enter the voids in the substrate, and may persist when flushing flows are limited (Klemm et al. 1990), resulting in prolonged effects on resident benthic macro-invertebrates.	Oil persistence in sediment depends upon oxygen availability (to promote biodegradation) and irrigating water flows (to promote weathering and toxicity reduction through removal of more soluble/bioavailable constituents). Spring freshet is a major seasonal factor that can flush river sediments, leading to a rapid restoration of damaged habitat.

Table 7-32 Effects of Oil on Benthic Macroinvertebrates by Oil Characteristic

Environment Characteristic	Low	Medium	High	Other Comments
Water flow characteristics	OPAs are most likely to be deposited in areas of slow-moving or still water. The slower natural biodegradation in depositional areas results in longer term habitat and toxicity effects on benthic macro-invertebrates, and longer time to community recovery.	OPAs may be locally deposited in areas of flowing water, but then re-mobilized under higher flow conditions and re-deposited elsewhere. Benthic communities in these areas recover more quickly due to faster removal of oil and faster recolonization from surrounding aquatic areas.	OPAs are not likely to be deposited in areas of turbulent flowing water. Lower oil deposition results in fewer and shorter term effects to benthic communities.	Sediment and water flow characteristics are frequently correlated (flowing water tends to have coarser-grained sediment, with less organic carbon, and standing water tends to have finer-grained sediment, with more sediment organic carbon).
Hyporheic (subsurface) flow systems	In streams that receive strong groundwater inflows, the net water flow away from the sediment will tend to prevent oil residues from entering the sediment and the hyporheic flow system, reducing potential effects on the benthic macro-invertebrate community.	Many streams have variable interactions with groundwater, both spatially and seasonally. Water may enter and exit from the hyporheic flow system at scales ranging from less than 1 m to 100 m or more. This can result in varying influences on oil effects to benthic macro-invertebrates.	In arid environments or during dry seasons, streams may regularly "lose" water to the hyporheic and groundwater systems. Under these conditions, dissolved hydrocarbons and very fine oil droplets may be entrained into the river bed or groundwater flow systems, and be resistant to degradation in low-oxygen environments, resulting in more prolonged effects of the oil on benthic macro-invertebrates.	The persistence of crude oil residues in hyporheic flow systems is likely to be low due to fresh water inflow, which will supply oxygen, and provide a flushing flow of clean water to remove relatively water soluble/bioavailable hydrocarbons, helping to reduce toxicity effects associated with the oil.

7.1.3.3 Fish

7.1.3.3.1 Description

Freshwater fish spend some or all of their life cycle stages in streams, rivers, ponds or lakes. As a group they have important ecological and economic functions. The trophic levels freshwater fish occupy range from herbivores to top predators, and the feeding ecology of individual fish may change as they grow from juvenile to adult life stages. Fish are an important food source for mammals such as river otter (*Lontra canadensis*) and American mink (*Neovison vison*), and for birds and waterfowl such as great blue heron (*Ardea herodias*) and common merganser (*Mergus merganser*), and raptors such as osprey (*Pandion haliaetus*) and bald eagle (*Haliaeetus leucocephalus*). Freshwater recreational fishing is a multi-billion dollar industry in North America. Traditional fisheries have been and remain an important food source for Aboriginal people, and in some locations are the basis for commercial fisheries.

Freshwater fish are often used as indicators of the health of a waterbody (Karr 1981), and fish surveys are used to determine both adverse effects and recovery from disturbance (Klemm 1993; Simon 1999). The advantages of fish for bio-monitoring are:

- Life span of fish, compared to benthic invertebrates, allows for longer term monitoring of effects
- Fish occupy multiple positions in the aquatic food web. An assemblage of fish usually includes omnivores, herbivores, insectivores, planktivores, and piscivores, allowing for monitoring across multiple trophic levels
- Fish are relatively easy to collect and identify, and depending upon the nature of the scientific analyses required, can be released unharmed
- Life history traits and environmental requirements of many fish species are relatively well known
- Many fish are important recreational and commercial species (Barbour et al. 1999; Klemm 1993)
- Fish can be one of the more sensitive indicators of water quality (Klemm 1993)

Federal and state agencies may collect fish community data as a measure of waterbody health, providing a robust record of waterbody status over time. Many states follow standard protocols for fish collection, often based on the USEPA Rapid Bioassessment Protocols for Use in Streams and Wadeable Rivers (Barbour et al. 1999). Collected fish are typically identified and counted and the data may be evaluated for a variety of metrics including abundance, diversity, species composition and dominance, and indicator species.

7.1.3.3.2 Observed Effects

Oil has the potential to affect fish directly through acute or chronic toxicity and indirectly by altering essential habitat (Enbridge 2015). Some components of oil (generally low molecular weight and aromatic compounds) may be acutely toxic when dissolved in water. Other components (e.g., higher molecular weight compounds such as parent and alkylated PAHs) may cause chronic toxicity when dissolved in water (Lee et al. 2015). Oil stranded on shorelines or deposited to sediments can release hydrocarbon compounds for weeks or months after an

accidental release. Contact between floating oil and shorelines will result in oiling of sediments at the water line. In addition, given the right conditions of turbulence and suspended sediment, almost any type of crude oil can become associated with sediment particles (i.e., as OPAs) leading to the deposition of some of the released oil to sediment, where flow conditions transition from moving to still water. The physical presence of oil on or in the substrates of water bodies may disrupt habitat use by fish. Clean-up activities may also disrupt habitat through removal of oiled substrates and riparian vegetation, or physical damage such as boat groundings, propeller wash, or fording of streams by wheeled vehicles.

Observed effects of released oil on fish were compiled from several case studies where oil was released in freshwater environments.

> ***Red Deer River, Alberta:*** *On June 7, 2012, approximately 3,000 barrels of light crude oil were released from a ruptured pipeline owned by Plains Midstream Canada ULC about 1.9 miles north of Sundre, Alberta and entered Jackson Creek, a tributary of the Red Deer River. Floodwaters 10 times higher than typical June flows eroded the stream bed and banks and exposed the pipeline under the river, which then ruptured (Alberta Energy Regulator 2014). Oil traveled at least 25 miles downstream to Gleniffer Lake reservoir, where booms contained the free oil product. Dissolved hydrocarbons in river water were detected up to 5 miles farther downstream (Alberta ESRD 2012a). Low molecular weight aromatic hydrocarbons (BTEX) and some PAHs were detected in the river and lake up to 30 miles downstream of the release location in the early days post-release (Alberta ERSD 2012a). Because of the high water levels at the time of the release, the majority of stranded oil occurred well above the high water mark for the river, in back water areas, trapped under trees and debris, in highly braided river margins, and mixed with silt and sediments (Teichreb 2014). Long-term monitoring showed that PAH concentrations in edible fish tissue were below human consumption guidelines (Teichreb 2014).*

> ***Marshall, Michigan:*** *On June 25 and 26, 2010, the Line 6B pipeline owned by Enbridge ruptured and released approximately 20,000 barrels of heavy crude oil, of which 8,000 barrels entered Talmadge Creek, a tributary to the Kalamazoo River, near Marshall, Michigan (NTSB 2012a). The released oil was a combination of Western Canadian Select (23%) and CLB (77%) diluted bitumens (Enbridge 2013a). The release occurred on the floodplain of Talmadge Creek, where wetlands are abundant (USFWS et al. 2015a). The Kalamazoo River is a meandering, low gradient river with diverse channel and floodplain features, extensive floodplain forests and wetlands, off-channel water bodies, and impoundments (Dollhopf et al. 2014). Oil was transported downstream in the Kalamazoo River, which was in flood state at the time of the release, to Morrow Lake (an impoundment in the river 36.5 miles downstream).*

Oil was deposited on river shoreline, riparian, and depositional areas (backwaters, side channels, oxbows) and along the shores of Morrow Lake (USFWS et al. 2015a), affecting 80 miles of shoreline and adjacent lands. There was associated disturbance from oil removal efforts (removal of riparian vegetation and sediment, access road construction; Dollhopf and Durno 2011). Some of the oil mixed with soil and organic matter while moving overland and also with suspended sediment in the water column, resulting in formation of OPAs that submerged in some locations, especially in depositional areas, and periodically released oil globules and sheen as late as 2014 (Fitzpatrick et al. 2015). Formation of OPAs was likely promoted by the flood conditions. Based on measurements of suspended sediment at the Marshall stream gage after the release, it can be inferred that the river had relatively low suspended sediment concentrations at the time of the release, but that the floodwaters likely increased the turbulence and the presence of suspended particulate matter (Fitzpatrick et al. 2015). In addition, the high organic matter content of the suspended and bottom sediments (20 percent or more) due to the abundant wetlands along the Kalamazoo River contributed to OPA formation (Fitzpatrick et al. 2015).

About 90% of the oil released into the river was recovered in the first year. This included floating oil, stranded oil in the floodplains of Talmadge Creek and the Kalamazoo River, and submerged oil (Fitzpatrick et al. 2015). In 2011, additional activities to dislodge and disperse submerged oil resulted in a small amount of additional recovery. Submerged oil-particle aggregates continued to release oil from sediments in the Kalamazoo River and impoundment areas during 2011–2014, with surface sheens observed in impounded sections of the river (Fitzpatrick et al. 2015).

During fish and wildlife response operations conducted by the MI DNR in 2010 for some sections of Talmadge Creek and the Kalamazoo River, 42 dead fish were found, which was considered a negligible number for this time period (USFWS et al. 2015a). Abundance and diversity of fish in Talmadge Creek decreased in 2010 post-release, but had recovered during subsequent surveys. Results of surveys conducted in 2011, 2012, and 2013 suggested there were changes in species composition, perhaps related to changes in habitat following clean-up (unpublished data provided to the Trustees for review for the Draft Damage Assessment and Restoration Plan [DARP], final results pending). Preliminary results for the Kalamazoo River were less definitive than for Talmadge Creek, with some reductions in smallmouth bass (Micropterus dolomieu) in 2010, but with variable results across all sites and years (USFWS et al. 2015a).

Sublethal effects on exposed fish (condition, tissue histopathology, immunotoxicity, induction of CYP1A, and a necropsy-based assessment of

health) were evaluated by the USGS during an August 2010 fish health assessment two months post-release (Papoulias et al. 2014). There were statistically significant differences for fish captured in affected areas of the Kalamazoo River compared to reference areas, indicating that fish in affected reaches up to 27 miles downstream of the release exhibited effects consistent with crude oil exposure. Follow-up studies on this topic were not completed.

Following the release, MI DCH put cautionary fish consumption advisories in place. Their analysis of fish collected in 2010 and 2011 determined that PAH concentrations in fish tissue were below levels that would necessitate fisher closure. However, consumption guidelines remained in place due to levels of mercury and polychlorinated biphenyls (PCBs) found in the fish tissue that were not related to the crude oil release (MI DCH 2014b).

Wabamun Lake, Alberta: *On August 3, 2005, a Canadian National Railway Company train derailed and released approximately 4,500 barrels of Heavy Fuel Oil 7013 (a Bunker C type fuel oil with a high viscosity and an initial density of about 0.99 at lake temperature) and 550 barrels of pole treating oil. About 20% of the released heavy fuel oil (940 barrels) travelled overland and entered Wabamun Lake; no appreciable volume of pole treating oil entered the lake (Hollebone et al. 2011). In the lake, the oil floated and spread rapidly over the surface; after a few days, strong winds and wave action dispersed the oil toward the north, east, and south shorelines, where it became entrained in macrophyte beds (Anderson 2006). While traveling overland, the oil mixed with soil and organic matter, and in the lake, aggregates, including tar balls, larger tar "logs," submerged sheets, large lumps, tar balls that sometimes reformed into oil slicks, and a "slurry" composed of finely divided organic matter and small oil droplets, formed quickly (Fingas et al. 2006, Hollebone et al. 2011). The aggregates showed a variety of behaviors, including submergence, neutral buoyancy, and resurfacing (Fingas et al. 2006), with extensive tar mat formation in some nearshore areas. Sinking oil settled in near-shore vegetated habitats where six out of eight native fish species in Wabanum Lake spawn including lake whitefish (Coregonus clupeaformis) and northern pike (Esox lucius) (Hodson 2008; DeBruyn et al. 2007). Behavior of oil in the lake (sinking, rapid formation of tar balls, slow degradation due to high proportions of high molecular weight components such as resins) and its toxicity and persistence (due to high PAH levels but low BTEX levels) were related to characteristics of the heavy fuel oil that would not be comparable to crude oils and diluted bitumen. Ultimately, clean-up activities recovered more than 95% of the oil.*

About 100 dead fish were observed in macrophyte beds following the release, including species of minnows and adult northern pike, lake whitefish, and burbot (Lota lota) (Birtwell 2008). Although these mortalities were attributed to natural

causes, and the Alberta Sustainable Resource Development ministry concluded the release had left no short term adverse effects on fish (Transportation Safety Board of Canada 2007), Birtwell (2008) argued that the 100 fish died as a result of the release, although toxicological tests to support this assertion were not conducted.

The shoreline macrophyte beds where oil accumulated are considered important habitat for several species of fish, particularly juvenile stages (Birtwell 2008). Direct fish mortality also occurred when vegetation was removed during clean-up activities. Fish habitat was disturbed or destroyed as a direct result of oiling in the macrophyte beds and also during clean-up activities (related to trampling, low-pressure flushing, vacuuming, and dragging over substrates).

In situ studies were conducted to evaluate potential effects of oil on spawning shoals of lake whitefish and northern pike. In November 2005, four months post-release, whitefish embryos were held in egg containers installed on affected and reference area shoals; survival and prevalence of deformities typical of oil exposure were measured (Debruyn et al. 2007). In general, fish from Wabamun Lake showed high baseline rates of deformities in both reference and affected areas, reflecting historical exposure to elevated concentrations of PAHs, related to public boating on the lake and presence of coal mines and coal fired power plants in the vicinity. However, at the conclusion of the study in April 2006, hatched survivors at the affected shoals had higher rates of severe skeletal deformities (statistically significant) compared to those from the reference area. PAH concentrations measured in passive membrane samplers adjacent to the egg containers were correlated with the rates of moderate to severe deformities (Debruyn et al. 2007). Similar exposure experiments with northern pike larvae resulted in few deformities, none of which could be attributed to PAH exposure, suggesting lower uptake of or sensitivity to PAHs in this species (DeBruyen et al. 2009).

Concerns over human consumption of fish containing hydrocarbons triggered fish tissue sampling and PAH analysis for one year post-release (Sandhu et al. 2008). Although PAH levels in tissue were elevated initially, it was suggested that these concentrations posed little or no risk of adverse effects to people consuming fish six months post-release (Sandhu et al. 2008). Ten years later, the Alberta Department of Fish and Wildlife reported that walleye (Sander vitreus) introduced into Wabamun Lake had become increasingly successful and that there were healthy populations of pike and perch in the lake (Hudson 2015).

Pine River, British Columbia: *On August 1, 2000, a Pembina Pipeline Corporation pipeline ruptured and released approximately 6,200 barrels of sour light crude oil, of which approximately 2,800 barrels entered the Pine River in British Columbia*

(BC MOE 2000a). The Pine River is a low gradient river, but fast flowing, and oil was dispersed up to 50 miles downstream. The fast flowing water allowed rapid dispersion of acutely toxic fractions of the oil. Oil was stranded and settled in depositional areas along the banks, in back eddies and other slow-flowing areas, and on organic debris and logjams (AMEC 2001 in Lee et al. 2015). Heavy rainfall later in August and September mobilized stranded oil, oil-contaminated debris, and sediments downstream; and high water levels scoured some of the more heavily oiled depositional areas. About 91% of the oil was recovered from the river or accounted for through volatilization over about two months (Alpine Environmental and EBA Engineering 2001 in Lee et al 2015). Some of the emergency response activities (e.g., removal of logjams and woody debris, altering of backchannels, bank armoring, and presence of heavy machinery in the river) also resulted in habitat damage (Summers 2004 in Bustard and Miles 2011). In August 1994, a small release of diesel fuel (151 barrels) and gasoline (187 barrels) had occurred in this area of the Pine River (Goldberg 2011).

Petroleum hydrocarbons were detected chemically, and seen and smelled in river water up to 50 miles downstream of the release, with sheen visible in back eddies and other calm areas along shorelines. Hydrocarbons accumulated in sediments and on organic debris (e.g., branches, leaves, and algae) present along the shoreline, in front of logjams, and attached to sweeper logs) in these calm areas (AMEC 2001 in Lee et al. 2015). Hydrocarbon concentrations in water decreased rapidly to below British Columbia water quality guidelines due to evaporation, dissolving in water, and natural dispersion (Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015), all of which are characteristic of light crude oil. Oil was observed to persist in some bottom substrates five years after the release (Goldberg 2006, as cited in Bustard and Miles 2011). Analysis of semi-permeable membrane devices deployed in the Pine River indicated that two years after the release, hydrocarbons were present in water, implying that hydrocarbons from the release were leaching out of sediment into the water column (DePennart et al. 2004), although additional sources (e.g., road runoff, PAHs from coal deposits in the watershed) were also acknowledged.

Although not measured directly, the initial release of crude oil into the Pine River was estimated to have resulted in hydrocarbon concentrations (water-soluble fraction likely greater than 3 mg/L) high enough to kill fish within hours of the release (Birtwell 2003 in Lee et al. 2015). Over the first five days post-release, 1,637 dead fish, mostly larger, more visible individuals, were found up to 30 miles downstream (Baccante 2000 in Birtwell 2008). Most were bottom-feeding species, consisting of 64% mountain whitefish (Prosopium williamsoni), 16% slimy sculpins (Cottus cognatus), and 5% burbot. The remainder were surface feeders, consisting of bull trout (Salvelinus confluentus), rainbow trout (Oncorhynchus mykiss), and Arctic grayling (Thymallus arcticus) (Baccante 2000 in Birtwell 2008).

Accurate direct counts of fish mortalities were difficult to make, given the challenges accessing areas of the river before fish decayed or were consumed by scavengers (Hodson et al. 2011). As a result, mortality was estimated using previous estimates of fish density and assumptions of mortality ranges. The mortality estimates ranged from 15,000 to 20,100 fish over a 19 mile section of river, and from 25,000 to 250,000 over a 30 mile stretch (Goldberg 2011). Eleven days after the release, British Columbia Ministry of Environment, Lands and Parks staff biologists reported fish returning to even the most affected areas of the river from adjacent tributaries (BC MOE 2000b).

Snorkel surveys conducted prior to the release (1993, before a small release of gasoline and diesel fuel in 1994) and post-release (2000, 2005, 2006, and 2007) were used to evaluate oil effects on sport fish abundance, species richness, and recovery of the community (Goldberg 2011). Survey results from 2000 demonstrated recruitment was occurring in the first two months post-release, but with lower fish abundance than in 1993 and with suckers absent. For sections of the river surveyed in 2005, 2006, and 2007, sport fish species composition and abundance appeared to have recovered to 1993 levels. Goldberg (2011) noted that with data available for only one survey pre-release, it was not possible to evaluate the inter-annual range of abundance but concluded: "results appear encouraging in that they are, at a minimum, similar to those observed in 1993, suggesting that the fisheries resources are exhibiting on-going recovery since the 2000 pipeline rupture and 1994 spill."

There were insufficient studies to establish the nature and extent of sublethal effects on reproduction and recruitment of fish. The concentrations of PAH compounds in fish stomach contents and bile confirmed PAH exposure via the food chain (Alpine Environmental and EBA Engineering 2001 in Lee et al. 2015). Concerns were also expressed about decreased benthic macroinvertebrate abundance, which provide food, especially for young fish during the first autumn post-release, which is a critical period leading up to overwintering (Birtwell 2008).

Cayuga Inlet, New York: *On November 3, 1997, a train derailed and released 167 barrels of diesel fuel into a first order reach of the Cayuga Inlet, which flows into Cayuga Lake, near West Danby, New York. Diesel fuel slicks escaped the containment booms and were observed within 24 hours on the surface of Cayuga Lake, 9.6 miles downstream (Lytle and Peckarsky 2001). One day post-release, a fish kill of rainbow trout (Oncorhyncus mykiss), white sucker (Catostomus commersoni), blacknose dace (Rhinichthys atratulus) and darters (Etheostoma spp.) was reported, estimated at 92% of total fish abundance in the inlet (Krueger in Lytle and Pekarsky 2001). Cayuga Inlet provides spawning habitat for rainbow trout (spring spawners) and brown trout (Salmo trutta) and salmon (Salmo salar), fall spawners that were beginning their autumn run when the*

release occurred. No information about effects on spawning salmonids was provided.

Asher Creek, Missouri: *In August 1979, a pipeline burst, releasing approximately 9,500 barrels of an unspecified type of crude oil into Asher Creek, in southwest Missouri, during low flow conditions (Crunkilton and Duchrow 1990). Dissolved oxygen, pH, and conductivity levels in water were not changed by the release (no information about hydrocarbons in water was published) and oil that entered substrates in riffle areas due to mixing was observed for over a year post-release (Crunkilton and Duchrow 1990). The creek originates in springs 0.4 miles upstream of the release site; low water volumes in these headwaters, particularly during summer, provided limited dilution of the oil, which would have increased the residence time of soluble oil components in sediment (Crunkilton and Duchrow 1990). Areas located downstream from surface skimming siphon dams were less severely affected and recovered more rapidly than areas closer to the release, where the substrate became inundated with oil (Crunkilton and Duchrow 1990). Following the release, an estimated 42,000 fish were found dead along a 5 mile section of the creek (Crunkilton and Duchrow 1990).*

7.1.3.3.3 Expected Effects of Released Oils

The effects of released oil on fish depend on characteristics of the oil and environmental conditions at the time of the release. Oil characteristics that may determine the acute effects of oil on fish include tendency to disperse in water, and concentrations of relatively water soluble components in the crude oil, particularly BTEX and low molecular weight PAHs. Chronic effects of crude oil in streams, rivers and lakes would depend more upon residual levels of total PAH (TPAH) in sediment and interstitial waters. Environmental characteristics include water flows, fish species sensitivity, and geomorphic factors that could lead to crude oil deposition in sediment. Effects associated with each characteristic are described in Table 7-33 and Table 7-34.

The potential for oil releases to harm fishery resources is well established, and documented in the case studies. Effects may be acute (e.g., fish kills) or chronic, leading to reduced population density and species richness, and associated potential effects on fish consumption due to increased PAH concentrations in tissue. Habitat disturbance during cleanup activities are another source of stress to fish populations.

Table 7-33 Effects of Oil on Fish by Oil Characteristic

BIOLOGICAL RECEPTOR: Fish and Fish Habitat				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Other Comments**
Viscosity	Low viscosity oils are readily dispersed as small droplets in the water column, when water is turbulent. Partitioning of hydrocarbons from small droplets into water as dissolved hydrocarbon is rapid, leading to high potential for acute toxicity to fish.	The viscosity of medium crude oils is relatively low, so these oils are also readily entrained into the water column, facilitating the dissolution of relatively water soluble components of the crude oil.	Heavy crude oils tend to have high viscosity, making them difficult to entrain into the water column, except under very strong mixing conditions (e.g., waterfalls and rapids). The viscosity of diluted bitumen is initially depressed by the added diluent, but as this weathers away, the viscosity of the weathered crude oil increases rapidly.	The viscosity of any crude oil will increase at low temperature. Viscosity also increases as crude oils weather.
Buoyancy	Light crude oils have low density, and are highly buoyant. Oil droplets entrained into the water column will therefore tend to re-surface rapidly, rejoining a surface slick, when water turbulence decreases.	Medium crude oils have intermediate density, and will typically not weather to a density equal to or greater than 1.0.	Heavy crude oils also have relatively high density. The density of fresh diluted bitumen is required by pipeline tariffs to be less than 0.94, but will increase with weathering after being released to the environment. Diluted bitumens float on water when fresh, and are likely to adhere to shorelines long before they would weather sufficiently to become neutrally buoyant in water (i.e., reach a density of 1.0). Some refined heavy oils (e.g., heavy fuel oils) may have initial density values very close to 1.0.	Density of crude oils will increase at low temperature, and also increases with weathering. Any type of crude oil may also interact with sediment particles (ranging in size from clays to gravels) resulting in an oil-mineral aggregate that has a density greater than 1.0. This can lead to crude oil becoming deposited to sediment.

Table 7-33 Effects of Oil on Fish by Oil Characteristic

BIOLOGICAL RECEPTOR: Fish and Fish Habitat				
Oil Characteristic	**Light Crude Oil**	**Medium Crude Oil**	**Heavy Crude Oil**	**Other Comments**
Chemistry	Low molecular weight aromatic hydrocarbon compounds (e.g., BTEX and some PAHs such as naphthalene) are usually the biggest contributors to acute toxicity. These compounds are often abundant in light crude oils. Light crude oils typically contain only small amounts of highly insoluble hydrocarbon components such as resins and asphaltenes.	Medium crude oils often contain moderate levels of BTEX and other relatively water soluble hydrocarbons, leading to a moderate potential to cause acute toxicity. Synthetic crude oils originating from the oil sands of Alberta may contain only small amounts of BTEX, as well as being depleted in resins and asphaltenes as a result of processing before shipment.	Heavy crude oils and bitumens are often highly weathered, containing only small amounts of BTEX, while containing larger amounts of polar compounds (resins) and asphaltenes. However, depending upon the nature and amount of the diluent added, diluted bitumens may contain levels of BTEX that are similar to light crude oils.	Acute toxicity of crude oils generally reflects the amount of low molecular weight hydrocarbons present (e.g., BTEX). Chronic toxicity reflects the amount of TPAH present. Most crude oils contain approximately 1% TPAH. Some refined oils such as heavy fuel oils contain larger amounts of TPAH (5-6% by weight).
Persistence	Light crude oils generally weather and biodegrade rapidly, and have low persistence in the environment, except when they become deposited in anaerobic environments.	Medium crude oils also weather and biodegrade quite readily.	Heavy crude oils can be resistant to weathering. Bitumen from the Alberta oil sands represents a type of crude oil that has undergone extensive natural weathering *in situ,* before it was extracted. Therefore, diluted bitumens tend to resist further weathering and biodegradation once the diluent component has been removed. This residual crude oil can therefore become a chronic low-level source of PAHs to the aquatic environment.	Any type of crude oil can be persistent if it is deposited in an environment where oxygen is not available. However, heavy crude oils and diluted bitumens contain more resins and asphaltenes than light and medium crude oils, and as a consequence, heavy crude oils tend to biodegrade more slowly, and have higher potential to become a persistent source of chronic, low-level hydrocarbon release to the aquatic environment.

Table 7-34 Effects of Oil on Fish by Environmental Characteristic

BIOLOGICAL RECEPTOR: Fish and Fish Habitat				
Environment Characteristic	**Low**	**Medium**	**High**	**Other Comments**
Water flow characteristics (turbulence)	Crude oils will float on still water, resulting in most of the low molecular weight hydrocarbons being lost to the atmosphere, rather than becoming dissolved in the water. Conditions leading to acute toxicity to fish are unlikely to occur.	Moderately flowing water may result in the entrainment of crude oils that have low viscosity (i.e., light and medium crude oils) into the water as small droplets. This creates conditions where low molecular weight hydrocarbons can more readily dissolve into the water column, potentially leading to acute toxicity to fish. More viscous oils may resist the process of entrainment, and remain floating on the surface of the water.	Highly turbulent flow conditions, such as rapids or waterfalls, will result in the entrainment of more viscous crude oils into the water column, creating conditions where these oil types are more likely to result in acute toxicity to fish.	Within a particular watercourse, flow rates and turbulence levels vary seasonally and in response to storm events. The highest seasonal flow rates in most systems occur during spring freshet.
Volume of water flow	Low water flow rates provide little dilution potential for hydrocarbons that dissolve into the water. Therefore, episodes of acute toxicity are more likely to occur in small streams, or during seasonal periods of low water flow rate (e.g., late summer and winter).		Large rivers have high water flow rates, which will reduce the potential for episodes of acute toxicity in the event of a crude oil release. High water flow rates also occur during the spring freshet.	Information from the case studies indicates that large-scale fish kills are more likely to be observed in streams and smaller rivers than in lakes and large rivers.

Table 7-34 Effects of Oil on Fish by Environmental Characteristic

BIOLOGICAL RECEPTOR: Fish and Fish Habitat				
Environment Characteristic	**Low**	**Medium**	**High**	**Other Comments**
Fish species and life-stage sensitivity	All else being equal, large-bodied fish are typically less sensitive to acute hydrocarbon exposures than small bodied fish. In addition, warm-water fish species are less sensitive than cold-water fish species.		Highly sensitive species are typically represented by small-bodied or juvenile fish. Cold-water fish species such as salmonids (trout and whitefish) are typically more sensitive than warm-water fish species (cyprinids, catfishes and sunfishes). Egg and embryo life stages are typically more sensitive than juvenile and adult life stages.	Toxicity assessment in risk assessment is typically based upon "sensitive" receptor species and life stages, on the assumption that if these receptors are protected, then all other similar receptors will also be protected.

The extent of fish mortality after a release is influenced by the type of oil (e.g., light crude oils will become dispersed and entrained into the water column as small droplets more readily than heavy crude oils, and may contain higher concentrations of low molecular weight hydrocarbons such as BTEX), the size of the receiving water body (a proxy for how much and how quickly dissolved hydrocarbons will become diluted or dispersed to non-lethal concentrations), and the presence of additional environmental stressors that could modify toxicity (Lee et al. 2015).

Fish can be exposed to acutely toxic hydrocarbon concentrations immediately following a release due to exposure to low molecular weight hydrocarbons. These fractions weather (through volatilization and biodegradation) and become diluted over 24 to 48 hours, so fish kills are often short-term and localized, unless there is an ongoing source of oil entering a system that provides little dilution. The low molecular weight hydrocarbons responsible for most of the acutely lethal effects are BTEX, low molecular weight PAHs like naphthalene, and short-chain alkanes (NRC 2005), which produce a narcotic effect on fish.

Bioaccumulation of PAHs in fish tissue can also lead to phototoxicity, which occurs when certain PAH compounds bioaccumulated in the tissues of receptor organisms are exposed to sufficient ultraviolet (UV) light to stimulate the formation of free radicals (Sellin Jeffries et al. 2013). The free radicals so formed can rapidly result in cell and tissue death, leading to the death of the organism. This is most likely to occur near the water surface, because UV light is attenuated with increasing depth in the water column by dissolved organic matter and suspended sediments. It is also more likely to occur during the summer months because day length and light intensity are greater, and light is not reflected or blocked by snow and ice, and in organisms such as juvenile fish that are small, weakly pigmented, and occur close to the water surface during daytime hours.

There are also sublethal effects on fish related to exposure to PAHs (including alkylated PAHs), avoidance of oiled areas, changes in feeding behaviour, developmental effects of PAH exposure on fish eggs and embryos, and delayed effects of such developmental effects such as reduced cardiac fitness in fish that survive embryonic exposure to crude oil (Lee et al. 2015, Incardona et al. 2015). Sublethal effects can include immune dysfunction (e.g., reduced macrophage activities), increased incidence of liver lesions (e.g., P450 [CYP1A] enzymes activity [specific hydrocarbon receptor]; Hudson et al. 2008), and other histopathological endpoints (Higgins 2002). Sublethal effects may also include behavioral endpoints such as impaired swimming in early life stages (Lee et al. 2015). The alkylated PAHs comprise 80 to 95% of total PAHs in crude and refined oils (Wang et al. 2003). They are less soluble in water, and take longer to dissolve in water, than the low molecular weight compounds. Oil stranded on or in sediments will continue to release alkylated PAHs to the water over weeks or months, resulting in ongoing exposure of fish to elevated PAH concentrations. However, within two weeks post-release, hydrocarbon concentrations in the water usually decrease to levels below which chronic effects to fish or other aquatic life would be expected (Stantec et al. 2012, Enbridge 2015).

Most species of fish can metabolize and excrete hydrocarbons, so these compounds do not bioaccumulate in the food web. Fish can rapidly take up water soluble low molecular weight hydrocarbons and release (depurate) them from their bodies when the source is removed (Hodson 2008). However, sensitivity to oil varies considerably among species of fish, related to differences in physiology, eating habits, biology, reproductive, and habitat preferences.

Although there are general trends in the relationship between concentrations of toxic compounds in various types of oils and their toxicity to fish, considerable variability has been identified in laboratory tests and field observations (Lee et al. 2015). For example, acute toxicity tends to be greatest for light crude oils (due to the high proportion of low molecular weight hydrocarbons they contain). Chronic toxicity tends to be greater for some heavy oils (particularly heavy fuel oils due to the high proportions of alkylated PAHs they contain). However, many exceptions have been noted and no definitive relationship between toxicity and concentrations of toxic compounds has been identified (Lee et al. 2015). Other factors that influence toxicity include the proportions of other high molecular weight compounds (e.g., waxes, resins, asphaltenes) that may help to determine physical characteristics of the oil (e.g., density, viscosity) that affect the physical behavior of the oil, as well as the bioavailability of the various classes of hydrocarbon compounds within the bulk oil.

Diluted bitumens contain both diluent (which may weather and disperse quickly) and bitumen (which is low in low molecular weight compounds and tends to persist in the aquatic environment). Chronic toxicity of bitumen is expected to be similar to that of conventional crude oils, given similarity in content of high molecular weight alkylated PAHs (Lee et al. 2015).

Exposure to oil stranded in sediments and related effects on abundance of benthic macroinvertebrate prey can lead to chronic and sublethal effects on fish, including effects on reproduction, growth and survival, which result in overall reduced fish production in areas affected by the release (reviewed in Dupuis and Ucan-Marin 2015 and Lee et al. 2015).

Table 7-33 and Table 7-34 provide a summary of the expected environmental effects of oil releases to fish. Table 7-33 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-34 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

7.1.3.4 Aquatic Plants

7.1.3.4.1 Description

Fassett (1957) defined aquatic plants as those that may, under normal conditions, germinate and grow with at least their base in the water, and that are large enough to be seen with the naked eye. For practical purposes, this definition provides a focus on aquatic vascular plants, and excludes unicellular algae. Filamentous algae can form large submerged or floating mats, and some macroalgae (e.g., the stoneworts, *Chara* and *Nitella*) common in hard water systems have the appearance and form of aquatic plants, but do not produce flowers, floating, or emergent leaves. Mosses, non-vascular plants that are often found in wet places (although not necessarily submerged), will be considered to be part of wetland ecosystems (e.g., bogs), and addressed elsewhere.

Aquatic plants provide many important ecosystem services.

- Energy Flow—aquatic plants are primary producers in the aquatic food chain, converting chemical nutrients in the water and soil into plant matter (Carpenter and Lodge 1986; Dodson et al. 2000).
- Food for Waterfowl and Fish—many submerged plants produce seeds and tubers that are eaten by waterfowl and other wildlife species. Insect larvae, snails, and crustaceans also thrive in plant beds, and these in turn serve as important foods for many wildlife and fish species (Valley et al 2004; MN DNR 2010a).
- Food and Medicinal Properties for Humans—many aquatic plants have been used traditionally for food and medicinal properties by humans. Wild rice (*Zizania aquatic*) is a grass, native to North America, which is an important traditional food to native Americans, and has become commercially important as well.
- Spawning Areas and Shelter for Fish—many fish species spawn in areas where aquatic plants grow or in marshy and flooded areas in early spring. During other times of the year, aquatic plants provide rearing habitat for juvenile fish, and cover for fish of all ages (Valley et al 2004; MN DNR 2010a).
- Improve Water Clarity and Quality—aquatic plants may help to maintain water clarity, and reduce erosion, by trapping suspended sediments and limiting the re-suspension of bottom sediments and some can absorb and break down polluting chemicals (Wolverton et al. 1975).
- Aesthetic Value—many aquatic plants such as reeds, cattails, water lilies, arrowhead, and pickerelweed have flowers or leaves that can be visually appealing in aquatic landscapes (MN DNR 2016a).
- Economic Value—as a natural and in some cases managed component of many water bodies, aquatic plants support the economic value of all aquatic related activities, including but not limited to camping, wildlife observation, hunting and fishing (MN DNR 2016a).

Freshwater aquatic plants are generally limited to shallow water or wetland habitats of lake and river systems.

7.1.3.4.1.1 Non-Vascular Plants

Algae have no true roots, stems or leaves and range in size from tiny, one-celled organisms to large, multi-celled plant-like organisms. Stoneworts (e.g., *Nitella* spp. and *Chara* spp.) are

examples of algae that look much like vascular plants and may grow in similar conditions. Other algae bearing less resemblance to vascular plants are also common. Mats of filamentous algae (e.g. *Spirogyra* spp. and *Cladophora* spp.) may cover the bottom in dense blankets, form "clouds", or rise to the surface under certain conditions. Planktonic algae (phytoplankton), which consist of free-floating microscopic plants, grow throughout the well-lit surface waters of lakes, ponds, and rivers.

Aquatic moss beds occur primarily in the riverine system and in permanently flooded and intermittently exposed parts of some lacustrine systems. Mosses (e.g., *Sphagnum* spp.) are also a major structural component of true bog ecosystems. Aquatic mosses are less common than algae or vascular plants but can often dominate vegetation in lakes (Sand-Jensen et al. 1999). The dominant types found in Minnesota include genera such as *Fontinalis, Amblystegium, Fissidens*, and *Drepanocladus* (Moyle 1937).

7.1.3.4.1.2 Vascular Plants

Aquatic plants may occur at any depth within the photic zone, although light attenuation in most natural water bodies is such that the productivity of the aquatic plant community is greatest in shallow water. Most aquatic plants are angiosperms, meaning that they produce flowers that must be pollinated, which requires that they be able to produce flowers at or above the water surface. Aquatic plants that are rooted in sediments may have both submerged and floating leaves, and the form of such leaves may differ. Being supported by water, aquatic plants are often delicate or fragile, and they often occur in sheltered areas where there is little water movement. In flowing water environments, their form may be streamlined or flattened in response to water movement (Wetzel 1975). Typical submerged genera include pondweeds (*Potamogeton* spp.*),* tape grass (*Vallisneria americana)*, water milfoil (*Myriophyllum* spp.), waterweed (*Elodea canadensis*), pipeworts (*Eriocaulon* spp.), and quillworts (*Isoetes* spp.). Common floating-leaved taxa include water lilies (*Nymphaea, Nuphar*), and water shield (*Brasenia schreberi*). Dimorphic species with distinctive submerged, floating or emergent leaves include lotus (*Nelumbo lutea*), duck potato (*Sagittaria* spp.) and floating-leaf pondweed (*Potamogeton natans*).

Not all vascular plants in aquatic bed communities are necessarily rooted. Aquatic plant species that may form free-floating masses include coontail (*Ceratophyllum demersum*), bladderworts (*Utricularia* spp.), and ivy-leaved duckweed (*Lemna trisulca*). Some non-rooted plants float and are found in areas with little or no current. Examples include duckweeds (*Lemna* spp.) and watermeal (*Wolffia columbiana*).

Emergent vascular plants are those that are rooted in sediment below the water level (sometimes at considerable depth), and which project leaves into the air above the water. Examples include cattails (*Typha* spp.), rushes (e.g., *Juncus* spp.), grasses and reeds (including but not limited to wild rice, *Zizania aquatica* and reed grass, *Phragmites* sp.), sedges (e.g., *Carex* spp., *Scirpus* spp.) and others.

7.1.3.4.2 Observed Effects of Oil on Aquatic Plants

Published reports specific to the effects of released oil on freshwater aquatic plants that can grow in temperate environments absent associated spill response activities are few in number. However, the general effects of oil directly on plants and indirectly through their growing media have been reported from various sources including laboratory and field experiments, experimental oil spills, and case studies of accidental oil spills (although such studies include the associated effects of response activities). Available data sources include observed effects of oil releases in marine, freshwater, terrestrial, arctic, and temperate environments, upland and wetland vegetation, and controlled and uncontrolled settings. This body of published studies provides a framework for inferring the likely effects to aquatic plants that may result from spills of oil into different aquatic systems.

Oil that directly contacts aquatic plants in large quantity can impede photosynthesis and gas exchange processes by blocking sunlight, clogging stomata, and raising internal temperature (Baker 1970; Emerson 1983; Michel and Rutherford 2013; Pezeshki et al. 2000). In addition, toxic compounds in the oil may burn sensitive plant tissues. When these conditions are of sufficient extent and duration, the direct toxicity or indirect loss of metabolic processes may cause death of the tissues (e.g., leaves) and potentially death of the whole plant. Such "burning" effects are more marked with light oils (or gasoline) than with heavier oils while "smothering" effects are more prominent with spills of heavy oils which are thicker and relatively more persistent in the environment.

Oil which contacts plants but does not kill by smothering can cause damage through biophysical and biochemical means (Currier 1951; Dallyn 1953; Baker 1970; Emerson 1983; Shales et al. 1989; Pezeshki et al. 1998). When oil adheres to and spreads over the plant surface, toxic compounds from the oil may enter the plant through stomata, by damaging and passing through the cuticle, or by entering plant roots through the soil. The rate and extent of penetration is affected by the number of stomata, resistance of the plant cuticle or root epidermis, and the viscosity of the oil. Plants with few stomata and thicker cuticles tend to be more resistant to oil penetration. Once in the plant, petroleum compounds move through intercellular spaces then through cell walls and plasma membranes, reducing transpiration, photosynthesis, movement of materials from leaves to other tissues, and altering respiration (Currier 1951; Dallyn 1953; Baker 1970; Emerson 1983). Internal physical damage can result when cell membranes are damaged by penetration of hydrocarbon molecules, leading to leakage of cell contents (Baker 1970; Shales et al. 1989). Biochemical effects may result from inhibition of enzyme reactions by toxic components of the oil, especially PAHs and water soluble components of the oil such as the BTEX compounds which can affect submerged tissues (Baker 1970; Shales et al. 1989).

Aquatic plants may also be affected by oil indirectly through water and sediments. In addition, the presence of degradable organic matter in the oil can lead to an increase in oxygen demand which, if there is no additional aeration, may lead to oxygen depletion and anoxic

conditions associated metabolic stress on aquatic organisms including plants (Shales et al. 1989; Kennedy et al. 1992; Summers et al. 2000; Edema et al. 2008; Edema 2012).

Potential damage to aquatic plants resulting from the incorporation of oil into sediment depends on the oil type and concentration. In general, light hydrocarbons have high acute toxicity to plants but, because of their rapid evaporation and/or dissolution, generally do not reach submerged sediments in concentrations which yield acute effects. Heavier hydrocarbon fractions have less acute toxicity to plants but can submerge and affect sediments due to their greater persistence in releasing toxic compounds (Shales et al. 1989; Overstreet and Galt 1995). Low concentrations of oil incorporated into soil and sediments have also, in some limited cases, been shown to stimulate growth of individual plant species perhaps by acting as a nutrient source or stimulator of nitrogen fixing organisms (Baker 1970; Snow and Rosenberg 1975a, 1975b; Burk 1977; Lin and Mendelssohn 1996; Mollard et al. 2012).

The type of waterbody can also affect the extent and duration of oil release effects to aquatic plants as a consequence of variations in dilution factors, flushing (or lack thereof), residence time, and aquatic plant community composition. Ponds and small lakes with standing water for example will have longer residence times, lower dilution factors, less physical disturbance, and greater magnitude and duration of impacts than large lakes or rivers characterized by large water volumes, wave action, and/or flushing (Baca et al. 1983, 1985).

Through its effects on individual plants, oil can alter plant communities by selectively killing or suppressing some plant species, allowing more tolerant species to colonize affected areas and become more abundant. Oil can also alter seed production, germination, and growth rates leading to further changes in plant community composition over time as a consequence of modified reproduction abilities (McCown and Deneke 1972; Burk 1977; Leck and Simpson 1992; Nicolotti and Egli 1998; Pezeshki et al. 1998; Pezeshki et al. 2000; Adam and Duncan 2002).

Currier and Peoples (1954) completed a laboratory study regarding the toxicity of hydrocarbons (n-hexane, hexene-1, cyclohexane, cyclohexene, and benzene) on various plants including the aquatic species elodea (*Anacharis canadensis)*. With respect to the elodea, saturated solutions of all the hydrocarbons except hexane killed quickly, at least within one hour. The hexane treated shoots showed no significant injury after 20 hours of exposure to the solution. Stepwise following trials led the researchers to conclude that: "On a per cent saturation basis, the increasing toxicity series is hexane, hexene, cyclohexane, cyclohexene, benzene. However, on a concentration basis the order is just the reverse."

Snow and Rosenberg (1975a, 1975b) studied the effects of experimental oil releases on the physical, chemica1, and biotic parameters of two sub-arctic lakes. Following the studies, they observed that:

> [T]he effects of crude oil on such lakes occur in three phases. The first is a period of acute toxicity which is of short duration (~ 2 days) and overlaps with a physically deleterious phase extending to several weeks. These effects may then

> be replaced by a chronic eutrophication, i.e., acceleration in rate of nutrient supply. The relative lengths and severity of each phase will be dependent upon such factors as volume of oil, type of oil, and climate.
>
> With respect to plant growth, periphytic filamentous blue-green algae were observed to have increased following the experimental oil spill, possibly in response to the addition of crude oil to the system as a nutrient source or stimulator of nitrogen-fixing organisms.

Hellebust et al. (1975) studied an experimental release of Norman Wells crude oil into Hanna lake near Norman Wells, NWT, Canada in order to evaluate the effects of crude oil on phytoplankton, periphyton, and attached macrophytes in terms of population composition, seasonal succession, and biomass. According to the researchers:

> The presence of crude oil had no significant effects on the total phytoplankton population, nor the seasonal succession of 20 common individual species except that some growth stimulation occurred in two blue-green algae, *Oscillatoria angustissima* and *O. tenuis.* Growth inhibition of the green alga *Ankistrodesmus braunii* was most noticeable at light intensities above and below those optimal for rapid growth. These findings show that the effects of an accidental oil spill on phytoplankton may be most serious if it occurs early or late in the growth season when temperature and light conditions are suboptimal for growth.
>
> In contrast to these minor effects of crude oil on phytoplankton abundance and species composition, algae growing on periphyton traps (i.e. species which normally grow on suspended particles or on the lake bottom) were strongly inhibited by the presence of oil. A probable reason for the inhibition of periphyton growth is that these algae, in contrast to the phytoplankton, were trapped on a solid substratum that also trapped oil components. The phytoplankton cells, which are free floating or swimming, were only exposed to dissolved oil components, which did not appear to be present in sufficient concentrations, possibly due to evaporation from the surface and microbial degradation, to cause significant adverse effects.
>
> Surface contact by crude oil of sedge, horsetail, and moss populations proved to be very damaging in terms of chlorophyll loss and extensive killing of the affected shoots. However, plant parts below the water level appeared to survive well, and this allowed considerable recovery of the plants by the next growing season.

Snow and Scott (1975) studied the effect and fate of Pembina and Norman Wells and crude oils respectively on Lakes 4C and 8 near Norman Wells, NWT, Canada. The researchers partitioned the lakes using plastic sheeting then introduced the crude oil to the center of one partition in each lake at a concentration of approximately 600 L/ha. With respect to aquatic plants, Snow and Scott found:

> The development of blue-green algae on experimental substrates in the areas of the lakes treated with crude oil was most striking. Coccoid blue-green algae were mixed with a dense mat of several morphologically different kinds of filamentous algae. Achlorophyllous filaments interwoven with the algae suggested that heterotrophic fungal filaments were present, although no fruiting bodies were observed. Blue-green algae were present in the control samples, though far less abundant. It is important to note that the samplers were at no time actually in contact with the oil in either lake; therefore, whatever the nature of the growth stimulant, it was present in the water itself. These data indicate that the presence of crude oil in a lake has a potentially eutrophying effect. The only dissolved nutrient measured which showed any significant change in the water of the oil spill section of each lake when compared to levels in the control areas following the spills was total dissolved nitrogen (TDN). … An increase in TDN in the oil spill sections of the lakes could occur through two main processes: firstly, by the dissolving of nitrogen contained in the oil itself, either by physical solution or via the intermediary of microorganisms, phytoplankton, or fungi; and secondly, from increased nitrogen fixation by indigenous oil stimulated lake biota.

Burk (1977) completed a four year study of vegetation following the release of approximately 1,000 gallons of fuel oil into a freshwater marsh within the Arcadia Wildlife Sanctuary near Northhampton, Massachusetts. At the end of the study, Burk reported that:

> Total plant cover, total number of species, mean number of species per quadrat and the Shannon-Wiener function progressively reduced in both high and mid-marsh zones for two years after the spillage. Eighteen of the species found before the spill were not found the following season. Perennial species generally were less affected than annual species immediately following the oil spill. Some species (e.g. *Dulichium arundinaceum* and *Eleocharis palustris*), declined in abundance the second season following the spill. Marked changes in relative abundance of the dominant species of high and mid marsh zones occurred from year to year, with *Onoclea sensibilis* more prominent in high marsh at the end of the study period than prior to the spill and *Pontederia cordata* and *Nuphar variegatum* more prominent in different segments of mid-marsh. The vegetation of the high marsh and mid-marsh zones had substantially recovered by the third and fourth years. The low marsh vegetation was apparently unaffected immediately following the oil spillage but in succeeding years the species diversity declined and luxuriant growth of *Elodea nuttallii*, *Potamogeton crispus* and *P. epihydrus* occurred.

Bott and Rogenmuser (1978) studied the effects of No. 2 fuel oil, Nigerian crude oil, and used crankcase oil to attached algal communities from Oldman's Creek, a tributary to the Delaware River in Glouster County, New Jersey. Communities were exposed to water extracts of the oils for

five weeks during the summer and five weeks during the fall. After the treatments, the researchers reported that:

> In both experiments, No. 2 fuel oil extract reduced biomass visibly, which was confirmed by lower chlorophyll a concentrations than those of the control. Species changes also occurred; bluegreen algae became dominant and diatoms became less important in community composition. Exposure to used crankcase oil extract also depressed biomass but microscopic observations and pigment ratios indicated that changes in dominant algal types were less dramatic than those with No. 2 fuel oil exposure. Communities exposed to Nigerian crude extracts possessed biomass comparable to the control.

Kauss et al. (1973) completed a two-year field and laboratory study of the toxicity of crude oil (mixed sour blend and seven western Canadian crude oils) to phytoplankton. The site chosen for field experiments was a small, oligotrophic pond located about 500 ft from the eastern shore of Lake Huron, near Douglas Point, Ontario. At the end of the study, the researchers observed:

> Field experiments have shown that a varying response can be expected from freshwater phytoplankton exposed to crude oil pollution. The response varies from inhibition to stimulation of growth. This is probably due to the interaction of biological and physical variables. Examples of biological variables are: composition of the algal community, the relative susceptibility of individual species and the availability of oil-degrading organisms. Physical factors would include the nutrient status of the water body, conditions of wind, temperature, insolation, etc.
>
> Experiments with *Chlorella* and *Chlamydomonas* have shown that a large part of the toxicity of aqueous crude oil extracts is due to compounds which are rapidly lost by volatilization. These compounds result in decreased growth and bicarbonate uptake of algal cells. These results suggest that the major toxicity of oil spills would be of short duration (considering only the effects of water soluble components).
>
> Marked stimulation of *Chlorella* growth in some oil extracts occurred after loss of toxic compounds. This may represent bacterial contamination of the oil extracts or an actual ability to utilize certain hydrocarbons. Literature evidence suggests the latter. It is noteworthy that the extract which most stimulated growth was outboard motor oil, composed mainly of paraffinic hydrocarbons. It is unlikely that the response of *Chlorella* and *Chlamydomonas* to water soluble components of oils is representative of all freshwater algae. Indeed, *Chlorella* may well be an oil tolerant species.

Ren et al. (1994) investigated the photoinduced toxicity of crude oil constituents (fluoranthene, pyrene, and naphthalene) to duckweed (*Lemna gibba*) in a laboratory setting. The researchers

found that fluoranthene and pyrene had a linear rate of growth inhibition with a threshold of impact at 0.5 µg/ml and a 50% of inhibition growth at 16 µg/ml. Conversely, naphthalene appeared essentially nontoxic to the duckweed, perhaps as a consequence of its greater volatility. The researchers then tested whether light intensity would modify the toxicity results and found that ultraviolet light enhanced the harmful effects of the chemicals. Based on these findings, they reported that:

> It is apparent that light will significantly increase they phytotoxicity of fluoranthene, pyrene, and naphthalene. Toxicity was increased both when the plants and the chemicals were incubated together and when the chemicals were pretreated with light then incubated with plant tissue. The only region of the solar spectrum that effectively enhanced toxicity was the UV. The order of toxic strength of the PAHs was correlated with the rate of photomodification of the chemicals thought it is suggested that the chemicals have photosensitization activity in the intact form as well.

McGlynn and Livingson (1997) studied the distribution of PAHs between aquatic plants and sediments using water hyssop (*Bacopa caroliniana)* and threadleaf arrowhead (*Sagittaria stagnorum*). The researchers found that:

> The effects of sediment PAHs (greater than 10 ppm) on growth were significant for both species. New growth of *B. caroliniana* was inversely associated with sediment PAH concentrations. The biomass, old growth, and new growth of *S. stagnorum* were also inversely related to sediment PAH concentration.
>
> PAHs are assimilated by the root systems of aquatic macrophytes and that the assimilation exhibits saturation effects and the presence of PAHs in the shoots of these plants is the result of root to shoot transport. Rooted rosette monocots assimilated significantly fewer PAHs from the sediments than did rooted vittate dicots. These differences might be attributed to the lignified structure of the dicot root system, and it might be inferred that this lignification leads to a reduction of either PAH binding sites or PAH entry channels. The lake data also indicate that nonrooted plants behave quite differently from rooted plants in that their PAH loads do not seem to correlate with sediment PAH concentrations.
>
> Aquatic plants grow well at sediment PAH concentrations over 1,000 times as concentrated as the sediment PAH concentrations at which aquatic fauna exhibit toxicological effects. At low sediment PAH concentrations, aquatic plants commonly achieve PAH tissue concentrations that exceed the sediment PAH concentrations. At high sediment PAH concentrations; however, aquatic plants cease to bioaccumulate sediment PAHs.

Marwood et al. (2001) studied the effects of coal tar creosote-derived PAHs on the growth of duckweed (*Lemna gibba*) and water milfoil (*Myriophyllum spicatum*) by measuring photosynthetic activity. The researchers reported that:

> The PAHs caused a 50% growth reduction in duckweed and milfoil at concentrations of 7.2 mg/L and 2.6 mg/L respectively. The results of this study using the PAM fluorescence technique support previous studies of PAH effects on electron transport. The different responses of the various chlorophyll-*a* fluorescence parameters, when taken together, support a mechanism of PAH toxicity in which photosynthetic efficiency was impaired as a result of general damage to essential cellular components, possibly from reactive oxygen species. Based on the loss of leaf chlorophyll in plants exposed to low PAH concentrations, destruction of chlorophyll pigments is apparently an important mechanism of PAH toxicity in plants and may precede damage to the proteins of the photosynthetic apparatus.

Akapo et al. (2011) studied the morphological and anatomical effects of Forcados Mix Nigerian crude oil at concentrations ranging from 10 to 100 ppm on water lettuce (*Pistia stratiotes*). Following the study, the researchers made several observations:

> The growth of water lettuce (*Pistia stratiotes*) is retrogressively affected by crude oil, and the effect is dependent on the concentration of crude oil in environment. All physical growth parameters measured (such as number of leaves, root length, leaf area, and number of sprouts) declined during growth in the presence of crude oil. The decline was shown to be concentration dependent. The THC accumulated in the roots was greater than in the leaves for all treatment and the roots of plants exposed to various concentration of crude oil were observed to shrink and detach. Shrinking was also concentration dependent. The rate of accumulation of lead and manganese and the total hydrocarbon content (THC) was seen to be greater at low concentrations and the rate decreased as concentration increased.

Lopes and Piedade (2014) performed an experimental study on the survival and response of water hyacinth (*Eichhornia crassipes*) when exposed to Urucu light Brazilian crude oil. The study applied six different oil doses ranging from 0 to 150 mL/L and five exposure times ranging from 1 to 20 days. Results of the study showed an inverse relationship between increasing concentrations of oil and exposure times, plant survival, and the number and sizes of leaves. The factors also interacted such that the effect of both together was larger than each individually. Anatomical modifications and alterations in cell organization were also observed in plants exposed to high concentrations. The researchers concluded that:

> Dose and time of exposure are two of the most important factors controlling the effects of Urucu petroleum hydrocarbons on *E. crassipes*. While relatively low

doses of oil may cause a reduction in the number of leaves and plant biomass, high doses can even cause death of the plants. The lower dose of Urucu oil tested, 3 mL/L, did not cause significant alteration in morphology and biomass of the plants. Moderate oil doses, 12.5 and 25 mL/L, caused an increase in dead biomass and a decrease in the ratio of live/dead biomass and number of leaves. When exposed to high doses, 75 and 150 mL/L, the decline in biomass and increase in plant mortality were intensified.

7.1.3.4.3 Expected Effects of Oil on Aquatic Plants

The effects of crude oil releases on aquatic plants depend upon the type of habitat into which the oil is introduced, as well as the type of oil and quantity released. In some cases (e.g., submerged weed beds), contact between released oil and aquatic plants may be avoided altogether. However, when contact does occur, aquatic plant response to oiling depends on the amount of the plant that is oiled, the resistance of the particular plant or plant tissue to petroleum compounds, the type of oil, and the duration of contact. Contact between crude oil and unprotected green tissues can be assumed to result in tissue (e.g., leaf) death, and potentially death of the whole plant. Plant stems may be protected by waxy cuticles, bark, or multiple layers of leafy material so that contact between oil and the plant stem may not result in serious harm to the plant.

Where aquatic plants are affected by oil, some general longer-term patterns resulting in community-level effects may also be expected:

- A reduction in aquatic plant growth while exposed to oil constituents (Burk 1977; Lin and Mendelssohn 1996; McGlynn and Livingston 1997; Marwood et al. 2001; Akapo et al. 2011; Mollard et al. 2012; Lopes and Piedade 2014)
- An increase in algal biomass and shifts in community composition (Snow and Rosenberg 1975a, 1975b; Hellebust et al. 1975; Snow and Scott 1975; Bott and Rogenmuser 1978; Kauss et al. 1973)
- A reduction in the relative abundance of floating plants, and increase in abundance of submerged aquatic plants such as *Elodea, Potomogeton,* and *Ceratophyllum* (Burk 1977)
- A reduction in the relative abundance of annual plants (Burk 1977; Leck and Simpson 1992)
- A decrease in overall community diversity, with a shift in dominance to more oil-tolerant species (Snow and Rosenberg 1975a, 1975b; Hellebust et al. 1975; Snow and Scott 1975; Burk 1977; Bott and Rogenmuser 1978; Kauss et al. 1973; Lin and Mendelssohn 1996; Marwood et al. 2001)

Light refined oils with high amounts of water-soluble fractions can cause acute mortality to aquatic plants, but these oils are likely to disperse and weather rapidly so that the effects may be short-lived (NOAA and API 1994). A spill of light crude oil or refined products would be expected to result in the death of most floating plants that come into direct contact with the material. Rooted floating-leaved plants would likely suffer growth reductions and dieback for one or two growing seasons but not outright mortality (Hellebust et al. 1975; Burk 1977; Lin and Mendelssohn 1996). Algal species, aquatic mosses, and submerged plants in the vicinity of a surface oil slick, but not in physical contact with the oil on the water surface, might suffer minimal

damage from dissolved chemical constituents of the oil (Hellebust et al. 1975; McGlynn and Livingson 1997).

Heavier oils tend to coat vegetation, although the vegetation may survive if the roots are not affected (Hellebust et al. 1975; Burk 1977; Baca et al. 1985; Lin and Mendelssohn 1996). These oils can persist for longer periods and may sink under certain conditions (e.g., due to formation of OPAs). Light oils may be more prone to formation of true OPAs, due to their lower viscosity and greater tendency to form small droplets entrained in the water column under turbulent flow conditions. However, this process also enhances microbial degradation of crude oil, and light crude oils tend to be less persistent than heavy crude oils. Oil that becomes incorporated into bottom sediments might affect plant roots (NOAA and API 1994).

Algal species, aquatic mosses, and submerged plants would likely suffer little or no damage unless the oil became submerged or sank. Some algae (e.g., cyanobacteria) may experience growth increases, likely in response to alteration in the availability of key plant nutrients.

Submerged aquatic plants contacted by submerged or sinking oil could experience reductions in growth. Should the oil be extensive and/or persist for an extended period, the plants could die and the oil could impede growth of new vegetation from the sediment. Where plants are damaged but not killed, regrowth in a growing season or two is likely for perennial plants while annual plants may require longer to recover, depending upon the timing of the spill with respect to seed set, as well as seed dispersal mechanisms and the extent of representation in the existing seed bank (Baker 1971; Burk 1977; Shales et al. 1989; Pezeshki et al. 1998).

Annual plants (e.g., wild rice) may be more severely affected, likely as a consequence of oil effects to seeds, seedlings, and/or reproductive organs that disproportionately affect species that rely on seeds for yearly growth (Baker 1971; McCown and Deneke 1972; Burk 1977; Shales et al 1989; Leck and Simpson 1992; Adam and Duncan 2002).

Perennial aquatic plants appear to be at least somewhat tolerant of dissolved oil constituents (Baker 1971; Burk 1977; Kauss et al. 1973; Baca et al. 1985). Therefore, some species of perennial rooted and floating plants, may experience some growth reduction but not death where toxic water soluable factions (WSFs) are in moderate to high concentrations, or in low concentrations for extended periods of time, as could be the case where there is submerged heavy oil (Snow and Rosenberg 1975a, 1975b; Hellebust et al. 1975; Snow and Scott 1975; Bott and Rogenmuser 1978; Kauss et al. 1973). There would likely be a short-term loss of productivity from diminished photosynthetic activity and growth (Carr et al. 1997). Short term reproduction is likely to be curtailed somewhat from spills during the growing season where there are energy losses and damages to reproductive structures.

Table 7-35 and Table 7-36 provide a summary of the expected environmental effects of oil releases to aquatic plants. Table 7-35 considers the effects of specific oil characteristics or oil type on the expected type and scope of environmental effects. Table 7-36 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-35 Biological Receptor: Aquatic Plants

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Comments
Density	Light crude oils have low density, and generally float on the water surface, where they can contact floating and emergent aquatic plants, or plants in shallow water along shorelines, while weathering rapidly. Even weathered light crude oil residues will normally float on fresh water. However, the WSF of oil may enter the water column.	Medium crude oils have intermediate density, and will float on the water surface, where contact with floating and emergent aquatic plants is likely. Medium crude oils will weather more slowly than light crude oils. These oils generally have a lower WSF than light crude oils.	Heavy crude oils generally have density values lower than that of fresh water, and will float if spilled. However, as they weather, their density may increase over time so that they eventually exceed the density of fresh water. Such oils would typically have high viscosity, and will not readily become entrained into the water column as fine droplets. Heavy crudes have the lowest WSF, so little dissolution is anticipated. However, these oils can form OPAs if the oil travels over soils or is discharged into waters with high suspended sediment loads and is well-mixed. OPAs which exceed a specific density of 1 may sink.	Fresh diluted bitumens have a density that should not exceed 0.94, although density will increase and may slightly exceed the density of fresh water given sufficient exposure to the elements, or formation of OPAs. With weathering, the viscosity of diluted bitumen increases rapidly, so that it becomes increasingly resistant to the formation of small droplets in turbulent water.
Viscosity	Light crude oils have low viscosity and may readily become entrained into the water column as small droplets by breaking waves. Low viscosity oils are more readily absorbed into plant tissues, causing acute damage. However they also have a lesser tendency to adhere to plants, and are less likely to persist in water and sediment resulting in relatively lower long-term chronic damage to associated plant communities.	Intermediate environmental behavior and effects based on specific oil constituents.	Greater tendency to adhere to plants causing smothering. Higher potential to sink and be persistent in sediment causing long-term chronic toxicity damage to associated plant communities.	Diluted bitumens that contain volatile diluents (e.g., gas condensate) can have similar concentrations of low molecular weight hydrocarbons to light crude oils.
Proportion of low molecular weight VOCs	Light crude oils usually contain a larger proportion of VOCs than heavier crude oils. The VOCs (which include mono-aromatic hydrocarbons such as the BTEX compounds) are potentially damaging to plant tissues on direct contact.	Intermediate acute toxicity depending upon relative proportion of BTEX and other low molecular weight hydrocarbons.	Heavy crude oils of natural origin may contain relatively low concentrations of BTEX and other low molecular weight hydrocarbons.	Diluted bitumens that contain volatile diluents (e.g., gas condensate) can have similar concentrations of low molecular weight hydrocarbons to light crude oils.

Table 7-36 Biological Receptor: Aquatic Plants

Environmental Characteristic	Low	Medium	High	Comments
Plant growth form	Submerged forms avoid direct contact with floating crude oil on the water surface. Submerged plants may suffer some indirect damage from water column contact with WSFs.	Free-floating plants would be killed if contacted by released oil. However, these plants also disperse readily, and can reproduce quickly by vegetative means. Floating-leaved rooted plants may suffer damage to leaves from direct contact with oil at the water surface, but may avoid damage to roots and rhizomes, allowing re-growth from root systems.	Leaves of emergent plants are typically protected from contact with released crude oil, and the limited contact of oil with stems at water level may not result in plant death. Many emergent plants also have energy storage tissues in the roots, and can survive damage to above-water tissues.	Wild rice is an annual emergent plant (a type of grass). It is possible that an oil spill that occurred as shoots were emerging from the water could result in tissue or plant death. Otherwise, if a release of crude oil occurred earlier or later in the growing season, wild rice plants might not be seriously affected. Plants having thick cuticles and/or few stomata would be less sensitive to released crude oil than plants with thin cuticles and/or many stomata.
Water depth	Shallow water provides less scope for dilution of water soluble fractions of crude oil, however, plants are not particularly sensitive to the water soluble fraction. However, a large proportion of plants in shallow water may be free-floating or have floating leaves, making them more susceptible to crude oil exposure on the surface.		Deep water provides greater dilution of WSFs. Plants located in deep water are more likely to have mainly submerged growth form, which would have low exposure to crude oil on the surface.	
Water currents	Stagnant or ponded areas provide little flushing and dispersal of released crude oil or water soluble components of the oil. This may result in greater oil thickness on the water surface, and longer duration of exposure for both floating and submerged aquatic plants.		Habitats with moving water (rivers) or water circulation (large lakes) provide greater flushing and dispersal of crude oil. Although larger areas of habitat may be affected, oil slicks may be thinner, and exposure may be of shorter duration.	During the Marshall, Michigan release of heavy crude oil to the Kalamazoo River in 2010, deposition of crude oil to sediments occurred mainly in areas of still water.
Plant lifespan	Annual plants that generally rely on seed production tend to be more sensitive to the presence of oil. If seed is not set, then these plants may not be able to grow in the following season (e.g., wild rice).		Perennial plants are more resistant to damage than annual plants. Even when vegetative tissues are damaged, perennial plants can re-grow from the root system, often within the same growing season.	Many aquatic plants have several means of reproduction, including seed production, root spreading and production of new shoots from rootstock, and vegetative reproduction from plant fragments that drift into new and potentially favorable habitats.
Plant age	Young plants may be susceptible to damage because they generally have more sensitive tissues, and have fewer energy stores.	Annual plants exposed to crude oil prior to seed set may still be sensitive, if the oil exposure prevents or inhibits seed set.	Mature rooted perennial plants would be less susceptible to damage because their roots would have low exposure to released oil, and are the site of energy storage from which the plant could re-grow. Annual plants post seed set would have low sensitivity as these plants would be senescent, and dying in any case.	

7.1.3.5 Amphibians and Reptiles

7.1.3.5.1 Description

Amphibians and reptiles are considered together as a group in this study because both classes of vertebrates are ectothermic (i.e., cold-blooded) species. In Minnesota, amphibians include frogs, toads, salamanders, and newts; and reptiles include snakes, lizards, and turtles. Effects of releases from oil pipelines are typically greatest in aquatic and riparian environments (NAS 2016); given that lizards and snakes are primarily terrestrial species with little or no association with aquatic environments, this assessment focuses on amphibians and turtles.

There are three key differences between reptiles and amphibians that have implications for potential effects of hydrocarbon releases. First, amphibians have porous skin that generally requires that they inhabit areas near water or damp environments; their porous skin may also facilitate dermal absorption of contaminants, an important exposure route. Reptiles have scaly, keratinous skin or shell (i.e., turtles) that is not porous and enables them to live in arid or hypersaline environments. Second, amphibians lay eggs that do not have a thick protective membrane or shell. Their eggs are laid in aquatic environments where they may absorb dissolved contaminants. Many amphibians are also external breeders meaning sperm is expelled into the aquatic environment and swim to eggs (Vitt and Caldwell 2013). In contrast, reptilian eggs have a leathery or shell membrane, and are laid in burrows where they are less predisposed to direct contaminant exposure. Some snakes do lay live young (viviparous) in cold climates (Vitt and Caldwell 2013). Finally, amphibians hatch from their eggs as tadpoles that are entirely aquatic with rudimentary gills used for respiration underwater. These juvenile amphibians undergo metamorphosis to become adults that are semi-aquatic organisms. On the other hand, juvenile reptiles hatch as small versions of their adult counterparts and are fully independent and capable of inhabiting aquatic or terrestrial environments.

As ectothermic individuals, amphibians and reptiles undergo a winter dormancy period when temperatures drop below approximately 41 to 45°F (Obbard and Brooks 1981; Tattersall and Ultsch 2008). Most aquatic reptiles and amphibians overwinter by burying themselves in mud and sediment of shallow lakes and wetlands. However, even in northern temperate regions some amphibians (e.g., ranid frogs) remain active in underwater environments where they are dependent on respiratory gas exchanges with the aquatic environment (Tattersall and Ultsch 2008).

As a group, amphibians and reptiles are omnivorous with some species' having a diet consisting primarily of invertebrates, and some species that are more predatory/carnivorous, while others subsist to a greater degree on vegetation. Juvenile reptiles typically feed on smaller prey (plant or animal) of the same trophic order as their adult counterparts; however juvenile amphibians (e.g., tadpoles) are more herbivorous and subsist on algae in early development (Kupferberg 1997).

Amphibians and aquatic reptiles typically respond to stressors through avoidance escape behavior seeking shelter in aquatic vegetation and benthos (Licht 1986). This avoidance may result in fewer amphibians and reptiles observed being affected by hydrocarbon releases. Unlike fish that will float to the surface when dead because of their air bladder, amphibians and reptiles will likely sink to the bottom and go undetected. Frogs are also prey for many species of fish, mammals, birds, other amphibians and reptiles, which could result in rapid scavenging of amphibians in some environments post-release.

There are no federally-listed amphibian or reptile species known to occur in Minnesota (USFWS 2016). However, under Minnesota's Endangered Species Statute (MN DNR 2013) there are 2 species listed as "endangered," 4 as "threatened," and 10 as "special concern." Of the semi-aquatic amphibian and turtles considered in this receptor group, Minnesota Endangered Species include:

- Northern cricket frog (*Acris blanchardi*) Endangered
- Blanding's turtle (*Emydoidea blandingii* Threatened
- Wood turtle (*Glyptemis insculpta)* Threatened
- Spotted salamander (*Ambystoma maculatum*) Special Concern
- Great Plains toad (*Anaxyrus cognatus*) Special Concern
- Four-toed salamander (*Hemidactylium scutatum*) Special Concern
- Mudpuppy (*Necturus maculosus*) Special Concern

7.1.3.5.2 Observed Effects

A review of several hydrocarbon releases from pipelines, and one resulting from a rail car accident, provided an overview of observed effects of releases on amphibians and reptiles in similar aquatic environments (e.g., river, lakes and wetlands) to those encountered in Minnesota. This review is not exhaustive, but provides a range of observed effects on amphibians and reptiles under different environmental conditions. While some of the case studies involve releases of light or medium crude oils, the effects are taken in context of the differences in properties of the oil types and provide some contrast of the potential effects among different oil types.

> ***Exxon Bayway****: On January 2, 1990, an Exxon underwater pipeline released approximately 13,500 barrels of No 2 heating oil into the Arthur Kill waterway at the mouth of Morse Creek between New Jersey and Staten Island, New York (NOAA 1992). Initial response efforts focused on containment of the release as well as removal of the larger masses of oil. Concentrations of floating oil and mousse in the open water, primarily between Howland Hook and Fresh Kills, were collected by self-propelled skimmers. Oil concentrated and stranded above the berm on the beaches from Cedar Point to Rossville. Environmentally sensitive areas were protected with boom and skimmers that collected the larger masses of free-floating oil. By February 20, 1990, monitoring crews reported nine terrapin turtles captured and released among other affected wildlife (NOAA 1992).*

***Lakehead**: On March 3, 1991, a Lakehead Pipeline Company, Inc. owned pipeline ruptured and released over 40,000 barrels of crude oil (NOAA 1992) approximately 2 miles north of Grand Rapids. Some of the oil flowed onto the 18 in. thick ice sheets on the Prairie River. Oil formed into 8-inch deep pools on top of the ice and was also present under the ice. Vacuum trucks were used by clean-up personnel to remove the oil from the ice surface. Workers used squeegees to push the oil along the ice to a removal location. Booms were used on the river by cutting a slot through the ice cover with chainsaws. Ice that had been permeated with oil was chopped into blocks small enough to be carried away to a separate part of the river. Clean-up personnel sprayed the ice blocks with hot water to wash out the oil, which was then recovered with skimmers. Blocks that were only slightly contaminated were moved to lined holding tanks and broken up. The crushed ice was then allowed to melt to recover residual oil. There were no reports of amphibians or reptiles injured during the post-release clean-up and monitoring, though the area would have been inhabited by several species. Overall effects to fish and wildlife were reported as minimal by the MN DNR (Telegraph Herald 1991), likely due to ice-covered conditions at the time of the release.*

***OSSA II:** On January 30, 2000, an estimated 29,000 barrels of mixed heavy crude oil and diluent (density of approximately 0.8 g/mL) were released from the OSSA II pipeline, operated by Transredes S.A., at the Rio Desaguadero river crossing in Bolivia as the river was rising to peak flood conditions (Lee et al. 2001, 2002; Owens and Henshaw 2002). Due to the very high river flow and water velocity conditions, and perhaps also due to the low viscosity of the oil, which would allow it to become dispersed into the water as fine droplets, oil was found up to 230 miles downstream from the release location. For the most part, the surface oil was deposited in strips, generally 3 to 6 ft wide and up to 0.5 to 1 inch thick. Many sections of river bank had a horizontal line of oil, "a bathtub ring" where the oil was deposited and stranded indicating the water level at the time (Owens and Henshaw 2002). The response effort included more than 3,600 people that recovered the oil within three months. Wasson et al. (2000 in Owens and Henshaw 2002) reported on the wildlife effects of the release and indicated that no wildlife fatalities other than a small number of birds were observed during the extensive post-release monitoring and clean-up.*

***Tinicum:** On February 5, 2000, a Sunoco pipeline cracked in Tinicum, Pennsylvania, releasing approximately 4,575 barrels of crude oil (USFWS 2009). The pipeline rupture was located at the eastern end of the John Heinz National Wildlife Refuge and flowed onto an ice-covered freshwater impoundment (Saba and Spotila 2003). It took approximately one month for clean-up crews to recover the oil, and before that was achieved, by February 17, the ice on the impoundment started to melt in some areas exposing aquatic species to the oil. Turtles started emerging and becoming coated in oil remaining on site before recovery had been completed. Tri-state bird rehabilitation center was contracted to recover, clean and rehabilitate oiled turtles. In total, there were 19 oiled turtles captured at the site. All captured turtles were cleaned, and*

monitored for one month during which time only one turtle died from apparent crude oil inhalation (Saba and Spotila 2003). The remaining 18 turtles were used in a study, along with a control group of turtles not exposed to oil to assess effects of oil exposure on survival and behavior. No effects of oil exposure were noted and the 18 turtles released survived (Saba and Spotila 2003). In total there are 19 species of reptiles and amphibians that use the John Heinz National Wildlife Refuge, but only the 19 individuals of four species of turtles were reportedly affected by the release.

Pine River: *On August 1, 2000, a pipeline operated by Pembina Pipelines failed and released approximately 6,200 barrels of light crude oil, of which an estimated 2,800 barrels entered the Pine River 70 miles upstream of Chetwynd, British Columbia. An estimated 300 to 710 barrels remained unaccounted for following the clean-up and remediation (BC MOE 2000a). Most of the unaccounted for oil was considered to be likely entrained in sediment or debris within the river. Response measures included placing two containment systems: one approximately 14 miles downstream and a second approximately 19 miles downstream (BC MOE 2000c). The river was flowing at a low stage at the time of the release (approximately 5,680 ft^3/s measured at a station 100 miles downstream, compared to flow rates above 31,880 ft^3/s during late spring and early summer). The Pine River has a gradient of approximately 0.225% in the first 25 miles downstream from the release location, decreasing to 0.1% farther downstream. There were reports from government staff and contracted clean-up crews of oiled wildlife (all birds), but no oiled amphibians or reptiles were reported (BC MOE 2000b).*

Wabamun Lake*: On August 3, 2005, a Canadian National freight train derailed near the Village of Whitewood Sands, Alberta, releasing approximately 4,500 barrels of Bunker C fuel oil (Heavy Fuel Oil 7102; Hollebone et al. 2011) and 550 barrels of pole treating oil. An estimated 950 barrels of the Bunker C oil entered Wabamun Lake and formed a thick black slick approximately 0.5 in. thick (Wernick et al. 2009).*

While traveling overland, the oil mixed with soil and organic matter, and in the lake, OPAs formed quickly, including small tar balls, larger tar "logs", submerged sheets, and large lumps (Fingas et al. 2006; Hollebone et al. 2011). The oil-sediment complexes exhibited a variety of behaviors including submergence, neutral buoyancy, and resurfacing (Fingas et al. 2006).

No dispersions of oil in water were observed in the lake, and no mousse formation was reported in the three years following the release (Hollebone et al. 2011). Overall, the water in the open water area of the lake was reported not to be contaminated with released hydrocarbons or associated metals (Anderson 2006). This is consistent with the very low concentration of relatively water-soluble components (such as BTEX) in the released oil, and the relatively low water solubility of this heavy oil. Similarly, sediments beneath the open water portions of Wabamun Lake were reported not to have been

contaminated with petroleum hydrocarbons and were considered to be of similar quality to concentrations measured in 2002 or shortly before the release (Anderson 2006).

Clean-up activities included cutting of the vegetation and vacuum removal of submerged tar balls entrained in the reed bed detritus (Wernick et al. 2009). A two year study was conducted to assess regrowth. The study found that exposure to the oil, which was released in the late growing season, did not cause large-scale changes to these emergent plant communities (Wernick et al. 2009). Physical factors such as clean-up activities and vegetation management appeared to be responsible for reduced regrowth observed at some locations (Wernick et al. 2009; Thormann and Bayley 2008). Despite an intensive wildlife monitoring program, and a wildlife recovery center set up immediately after the release, there were no reports of amphibians or reptiles injured by the oil (TSBC 2007).The area would have been inhabited by several species of amphibians and reptiles.

***Glenavon**: On April 15, 2007, a release occurred on the Enbridge Line 3 pipeline approximately 1 mile downstream of the Glenavon pump station near Glenavon, Saskatchewan. The rupture released approximately 6,200 barrels of heavy crude oil and affected approximately 5 acres of a wetland on farmland (TSBC 2008a; SLR Consulting 2008a). Within two days of the release, approximately half of the crude oil had been recovered (Canada.com 2007a). In April 2007, surface water samples from the affected wetland exceeded applicable guidelines for hydrocarbons and total metal concentrations and background, and exceeded concentrations from nearby reference wetlands (SLR Consulting 2008a). As remediation actions, the affected surface water (approximately 1.8 million gallons) was collected and disposed in approved wastewater facilities (SLR Consulting 2008a). These activities were complete in early May 2007, and surface water samples conducted in August had concentrations below guidelines (SLR Consulting 2008a). The site was monitored for one week for exposure of wildlife to oil, and wetlands within 0.6 miles (1 km) were surveyed for any wildlife that may have been oiled initially and moved away from the release site. The only reported injured wildlife were birds (SLR Consulting 2008a); there were no reports of injured or dead amphibians or reptiles, though amphibians would have inhabited the wetland.*

***Marshall**: On July 25, 2010, Enbridge's Line 6B pipeline experienced a release in a wetland near Marshall, Michigan. Approximately 20,000 barrels of heavy crude oil containing diluted bitumen were released over a period of about 17 hours. The pipeline contained two different batches of crude oil at the time of the release. It is estimated that the released oil consisted of approximately 77% CLWB diluted bitumen and 23% Western Canadian Select, also diluted bitumen (NTSB 2012a). Of this, approximately 8,200 barrels reached Talmadge Creek and the Kalamazoo River (Enbridge 2013a). Talmadge Creek was flowing with higher than normal flow due to recent heavy rains. The crude oil flowed down Talmadge Creek to the confluence with the Kalamazoo River, and then into the Kalamazoo River. Due to the elevated water level, the crude oil affected*

floodplain areas on both sides of Talmadge Creek. The river was also high at the time of the release and had overflowed its banks in many areas. As a result, oil entered the floodplain areas. As water levels in the river receded, much of the crude oil flowed with the flooding water back within the banks of the Kalamazoo River, although crude oil also became stranded in hydrologically isolated areas such as depressions, cavities, burrows, and other traps within the riparian zone (Enbridge 2013a). These conditions resulted in oil being stranded in areas that would be suitable habitat for amphibians and reptiles. As a result, 106 reptiles were found dead or subsequently died during rehabilitation, and approximately 3,931 turtles and 73 amphibians were captured, treated and released (USFWS et al. 2015a). Many (over 600) of the oiled and captured turtles were recaptured at least once, which suggests that the oiling effects were relatively benign (Lee et al. 2015). The primary species affected were common map turtles (77%), snapping turtles (11%), painted turtles (6%), and eastern spiny softshell turtles (3%). Other species included common musk, Blanding's, eastern box, and spotted turtles (USFWS et al 2015 a).

***Rainbow Pipeline, Alberta, Canada**: On April 28, 2011, approximately 28,300 barrels of sweet crude oil were released from a Plains Midstream Canada pipeline into a muskeg/stagnant water area near the community of Little Buffalo in the Peace River region of Alberta. The release occurred on a hillside, and the oil flowed a half mile down the pipeline ROW and pooled in a low-lying area containing abandoned beaver ponds. The release encompassed an area of approximately 20 acres (ERCB 2013). During response activities, perimeter fencing and wildlife deterrents (including eagle kites and bear-scare canyons) were used to prevent wildlife from entering the release site (ERCB 2013). However, over the course of the following 18 months (i.e., by November, 2012) 12 amphibians (11 frogs and one toad) were found deceased (ERCB 2013). No cause-of-mortality analysis was conducted for the deceased wildlife, but it is presumed that oiling was the likely cause.*

***2011 Yellowstone River**: On July 1, 2011, flood conditions in the Yellowstone River resulted in a release from the ExxonMobil Silvertip Pipeline near Laurel, Montana. Riverbed erosion had exposed the 12 inch pipeline beneath the crossing, and debris caught on the washed-out pipeline caused excessive stress, resulting in a clean break. The failure was detected at the pipeline control center and the line was shut down within 10 minutes (USDOT 2012). Approximately 1,500 barrels of medium sour crude oil were released into the Yellowstone River (USDOT 2012). High flood flows carried the oil downstream and prevented it from settling on the river bottom. Crude oil affected primarily shorelines and banks immediately downstream of the release site (MT DEQ 2015b). A pocket of emulsified oil was found approximately 72 miles downstream, but the majority of the release effects were observed within 20 miles of the release location (USEPA 2011). Search efforts found two toads that were captured and cleaned and two additional oiled toads and one garter snake were observed, but not captured (USEPA 2011).*

***Red Deer River**: On June 7, 2012 a Plains Midstream Canada ULC (Plains) pipeline released, as a result of high water levels in the river, approximately 2,900 barrels of light crude oil into the Red Deer River downstream of Sundre, Alberta (AER 2014). The migration of visible oil was stopped by booms placed at Gleniffer Lake, but dissolved hydrocarbons continued to move downstream. This resulted in potential toxic and oiling effects upstream of the booms, and toxic effects downstream of the booms in Gleniffer Lake (Teichreb 2014). Officials with Alberta Environment indicated that effects to wildlife were minimal (Derworiz 2012). During the post-release clean-up, there were no reports of amphibians or reptiles injured and monitoring, though the area would have been inhabited by several species of amphibians and reptiles.*

***Line 37**: On June 22, 2013, unusually heavy rains resulted in ground movement that compromised the integrity of the Enbridge Line 37 pipeline, approximately 1 mile north of the terminal in Cheecham, Alberta. The resulting failure released approximately 1,300 barrels of synthetic light crude oil underground with some oil seeping to the surface where it flowed overland entering a wetland and unnamed lake (Enbridge 2013c). Initial clean-up and remediation recovered 93% of the crude oil with the remaining oil found in soils and a fen. During the post-release clean-up and monitoring, there were no reports of amphibians or reptiles injured (Focus Wildlife Canada 2013), though the area would have been inhabited by several species of amphibians, and, possibly, reptiles.*

***Mid Valley**: On October 13, 2014, an oil release from a Sunoco Logistics Partners pipeline occurred near Mooringsport, Louisiana. Approximately 4,500 barrels of sweet crude oil were released into the Miller branch of the Tete Bayou, which feeds into Caddo Lake. Although containment booms prevented the oil from entering Caddo Lake, approximately 10 miles of the creek were affected by the release. Initial media reports were that approximately 66 animals, including 30 fish, crayfish and 10 reptiles died as a result of the release (Welborn 2014a). Later media reports about one month following the release were that 486 dead animals were collected and 47 cleaned and released (Welborn 2014b). Most of the animals were crawfish and amphibians, but species and specific numbers were not provided (Welborn 2014b).*

***2015 Yellowstone River**: On January 17, 2015, a pipeline owned by Bridger Pipeline Co. released approximately 715 barrels of Bakken crude oil (estimates ranged from 300 to 1,200 barrels) into the Yellowstone River approximately 5 miles upstream of Glendive, Montana (MT DEQ 2015b). The breach in the pipeline occurred where the pipeline crossed under the river. Winter conditions resulted in extensive ice cover, but aerial patrols discovered oil as far as 25 miles downstream of Glendive, (The Guardian 2015). Booms were deployed on the ice to collect oil from the surface but winter conditions combined with thawing resulted in unsafe working conditions and only a limited amount of oil could be recovered from the river (approximately 60 barrels) (MT DEQ 2015a). There were no reports of oiled wildlife (including amphibians or reptiles) or dead fish (Stuart 2015). The Montana Departments of Natural Resources and Conservation; and Fish,*

> *Wildlife and Parks expressed concern that the most significant source of damage to the riverine system was the physical damage caused by response crews and equipment during clean-up operations.*

7.1.3.5.3 Expected Effects of Released Oils

Compared to birds and semi-aquatic mammals, effects of oil and PAHs on amphibians and reptiles is less well understood, particularly for inland freshwater species (Albers 2003; Malcolm and Shore 2003; Lee et al. 2015). Reported injuries to amphibians and reptiles from hydrocarbon releases suggest that semi-aquatic amphibians and reptiles are regularly affected species, though most likely go undetected. The extent of injuries varies and fatal injuries were more common in amphibians than in reptiles. Amphibians are generally smaller organisms than birds, mammals or even reptiles, and their propensity to seek shelter in sediment or aquatic vegetation when disturbed may result in fewer affected individuals being detected following a hydrocarbon release. Furthermore, smaller organisms are often not detected because of scavenging by predators. There are no reports of studies assessing detection or scavenging rates for amphibians. However, bird scavenging rates tend to be higher for smaller species and detection rates of individuals present lower than that of larger species (Ponce et al. 2010), and this likely would apply to other species groups as well.

There are few published studies about effects of crude oil, particularly diluted or synthetic bitumen and heavy crude oils, or hydrocarbons on amphibians and reptiles. Like other vertebrate species (i.e., mammals and birds), effects can be classified into direct physical effects, direct toxicological effects, and indirect effects. The observed effects of hydrocarbons on amphibians or reptiles are variable and likely due to differences in search effort, release environment, species present, and time of year. Generalizations about effects on amphibians and reptiles are challenging to draw based on limited research for this species group. In some case studies, reported injuries were primarily fatalities (e.g., Mid-valley release) and consisted mostly of amphibians, while in other case studies injuries were generally minor with most captured individuals treated and released (e.g., Marshall and Tinicum releases). The Mid-Valley release where most reported injuries were fatalities, consisted of light crude, whereas the Marshall release, where thousands of individuals were captured and rehabilitated, was heavy crude. The mode of action causing fatalities is challenging to determine without conducting necropsies, and the difference between the two releases could be due to difference in toxicity of the oil components or differences in the physical properties. The magnitude of effect is also difficult to interpret when estimates of population size are not available against which to compare injury rates. Based on two case studies where turtles were oiled and monitored (Marshall and Tinicum releases), the population viability of turtles is not affected by oil releases in freshwater environments.

7.1.3.5.3.1 Direct Physical Effects on Amphibians and Reptiles

Direct physical effects generally involve adhesion (i.e., oiling) of exposed individuals. For amphibians, oiling would occur primarily in the adult stage when individuals are more terrestrial and frequent the water surface and shorelines; eggs and tadpoles are generally submerged

and would not be as readily oiled. Because reptiles transition between aquatic and terrestrial environments at all life stages, oiling could affect juveniles to the same extent as adults. However, reports of injured or oiled amphibians and reptiles in case studies did not identify the age of individuals.

Saba and Spotila (2003) found that oiled adult turtles had no difference in survival or home range size than non-oiled individuals. This is consistent with reports of approximately 3,900 turtles being captured, cleaned and released following the Marshall release into the Kalamazoo River, as many individuals (n = 622) were recaptured up to five times (USFWS et al. 2015a). This recapture rate suggests that the physical effects of oiling from diluted bitumen are relatively benign (Lee et al. 2015). During the clean-up of the Marshall release 73 oiled amphibians were also captured, treated and released. Given the smaller size of amphibians and their propensity to seek shelter underwater, it is possible that oiling of frogs, toads and other amphibians would lead to individuals not being detected or recovered following a release. Oiling of amphibians and reptiles would also be limited to the active period of spring, summer and early fall as hibernating individuals buried in sediment would not be exposed to oil, as was the case in the release at the John Heinz National Wildlife Refuge where three weeks passed before ice melted and emerging turtles came in contact with the exposed oil at the water surface (Saba and Spotila 2003). One exception might be ranid frogs that are partially active underwater during the winter period. These individuals may be exposed to oil under ice of shallow lakes and rivers, if the release occurred in the winter. Oiling of reptile eggs, particularly turtles, may occur if oil permeates sandy beaches where turtles are known to dig nests to bury their eggs for incubation. Oiling of eggs may create barriers to respiration and cause the embryos to die, though distinguishing physical effects from toxic effects on eggs is difficult (Rowe and Mitchelmore 2009).

7.1.3.5.3.2 Direct Toxicological Effects on Amphibians and Reptiles

The response of amphibians and reptiles to hydrocarbon exposure has not been well studied (Albers 2003; Malcolm and Shore 2003; Lee et al. 2015). Reptiles are likely to be exposed primarily through consumption of contaminated food, direct ingestion of oil and/or inhalation of volatile hydrocarbons. These same exposure pathways would apply to amphibians that would also have higher exposure than reptiles through dermal absorption. The soft skin of amphibians would make them more susceptible to dermal exposure of dissolved hydrocarbons in the aquatic environment (Stabenau et al. 2006). Amphibian embryos have been described as slightly less sensitive to fuel oils and crude oils as fish embryos, and mortality in amphibians is most common in late-stage developing tadpoles (Albers 2003).

Studies on the effect of hydrocarbons on turtles from the John Heinz National Wildlife Refuge demonstrated that there was no difference in post-release survival, home range, or water temperature preference among exposed and non-exposed turtles (Saba and Spotila 2003). Subsequent studies reported that female snapping or painted turtles exposed to crude oil did not have lower fertility, or clutch size, but there was a measured effect on embryonic

development, though the source of the hydrocarbons is questionable because of historic site contamination (Bell 2005; Bell et al. 2006).

Studies examining the effect of petroleum hydrocarbons on hatching and growth of frog eggs found that while hatching success did not decrease in one study (Mahaney 1994), which may be attributed to the protective jelly coat of eggs, Marquis et al. (2006) noted that effects on hatching and the protective jelly coat is species-specific and not applicable to all species. Mahaney (1994) also reported that tadpole growth was also affected increasingly with higher concentrations of dissolved oil, although his study used crankcase oil, which contained a similar proportion of aromatic hydrocarbons as heavy crudes and diluted bitumens (~20%). Similarly, results from a study examining hatching success and embryo deformity rates of turtle eggs exposed to oil depended on the specific population from which individuals originated (Van Meter et al. 2006). Hydrocarbon releases into the aquatic environment that result in lower concentrations of dissolved hydrocarbons, and in PAHs, would likely result in reduced effects on egg survival and tadpole growth. Diluted bitumens have lower quantities of BTEX, USEPA priority PAHs, and total alkylated PAHs than do conventional crude oils, and have been shown to have lower or equal toxicity in zebrafish studies (NRC 2003; Zhou et al. 2015). This suggests that toxicity of diluted bitumens would have equal or lower toxicity to amphibians and reptiles adults and eggs. Moreover, evidence suggests that even light crude oil tested in experimental studies resulted in no biological effects on diamondback terrapin or snapping turtle egg survival or other biological endpoints of hatchlings after 13 months (Rowe and Mitchelmore 2009).

7.1.3.5.3.3 Indirect Effects of Oil Release on Amphibians and Reptiles

Indirect effects occur over longer term and are the result of loss of habitat, increased predation risk, or change in food abundance or availability. Loss of vegetation, and effects to local populations of algae, invertebrates or fish could have long-term effects on the survival and reproduction, and, therefore, on population abundance of amphibians and reptiles. The remedial actions taken in response to hydrocarbon concentrations exceeding guidelines from the Glenavon release likely resulted in effects to amphibian habitat, particularly where remediation activities occurred during the breeding season of species like the northern leopard frog. Wetland drainage is considered a high concern activity for this species (Environment Canada 2013). Vegetation removal and clean-up of the Wabamun release likely affected habitat for several amphibian species both as eggs, juveniles and adults, though this effect would have likely lasted only until vegetation regrowth occurred in the wetland areas the following year.

Mahaney (1994) reported that hydrocarbons from crankcase oil had a negative effect on algal growth rates. The hydrocarbon composition of crankcase oil (20% aromatic, 80% aliphatic) reported in this study is similar to heavy crude oils and diluted bitumens (Dupuis and Ucan-Marin 2015; Zhou et al. 2015), and the expected effects might be similar. However, water quality monitoring following the Wabamun Lake release indicated that water and sediment quality parameters measured in the open water portion of the lake did not indicate any contamination by hydrocarbons, and therefore algal populations were likely not affected by this release.

Table 7-37 Biological Receptor: Amphibians and Reptiles

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—buoyancy	Light crude oils typically have a low relatively density (0.78-0.88 g/mL, Dupuis and Ucan-Marin 2015) and are buoyant in freshwater aquatic environments.	Medium crude oils typically have an intermediate density compared to light and heavy crudes, and are buoyant in freshwater aquatic environments (Dupuis and Ucan-Marin 2015).	Heavy conventional crude oils can have density ranging of 0.88 to 1.00 g/mL, while diluted bitumen will have density less than 0.94 g/mL (Dupuis and Ucan-Marin 2015).	Density of crude oils will increase over time with weathering. It has been suggested (NAS 2016) that diluted bitumen will rapidly weather to a state where its density will exceed the density of fresh water. However, this conclusion is based on data from a high-temperature rotary evaporation procedure, which both accelerates weathering and drives it to an endpoint that may not be reached in a relevant period of time under more realistic environmental conditions. Lee et al. (2015) concluded that "evaporative mass losses of <20% after rigorous weathering at environmentally-relevant temperatures for dilbits nominally comprising ≥30% diluent suggests that a substantial proportion of diluent remains intimately associated with bitumen". This will mitigate against sinking behavior of diluted bitumen in fresh water. These details are further discussed in Section 7.1.2. Recovery or released oil is facilitated if the oil floats on the surface of the water. More rapid recovery of oil will result in a reduced duration of potential exposure, and will avoid contact with submerged amphibians and reptiles.
Oil properties—viscosity	Light crudes will spread rapidly on water because of their low viscosity (1 to 5 mPa•s, NAS 2016).	Medium crudes have an intermediate viscosity (8 to 112 mPa•s, NAS 2016).	Heavy crudes (820 to 475,000 mPa•s) and diluted bitumens (270 to 50,000 mPa•s) weather to high viscosity (NAS 2016). Of note, the viscosity of fresh bitumen is reduced by the addition of diluent (referred to as diluted bitumen), to conform to pipeline specifications.	Viscosity is a function of oil chemistry. Diluted bitumens tend to display a more rapid increase in viscosity due to weathering than conventional heavy crude oils as a result of the rapid initial evaporation of some of the diluent. Oil having low viscosity will rapidly spread across the water surface forming a thin and relatively uniform slick that may result in a larger area where amphibians and reptiles may be exposed to released oil. More viscous oils will spread more slowly and may exhibit thicker but patchier slicks with associated sheens. This would allow for some areas to serve as refuges for amphibians and reptiles in an aquatic system.

Table 7-37 Biological Receptor: Amphibians and Reptiles

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—adhesion	Light crudes have low adhesion and viscosity (NAS 2016) and lower quantities of oil will adhere to amphibians and reptiles exposed to released oil.	Medium crudes have an intermediate adhesion and viscosity (NAS 2016). Lower quantities of medium crude will adhere to amphibians and reptiles exposed to released oil.	Heavy crudes and diluted bitumens are highly adhesive and more viscous than light and medium crude oils. When fresh, diluted bitumens have relatively low viscosity, and would penetrate feathers. However, weathered heavy crudes may tend to adhere to amphibians and reptiles.	Properties of adhesion and viscosity may change the way that crude oil interacts with wildlife through adhering to the exterior of individuals. Light oils form thin layers on surfaces and would be more easily cleaned or removed from the skin or surface of amphibians and reptiles than heavier oils.
Oil chemistry—toxic constituents	Light crude oils often contain high levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, depending on the oil type, but can be high (>10,000 mg/kg) in Bakken oils.	Medium crude oils often contain moderate levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, but can exceed 10,000 mg/kg.	Levels of BTEX and other relatively water soluble constituents are variable: generally low in heavy conventional oils, but variable in diluted bitumens depending upon the nature of the diluent. Levels of TPAH are variable, but typically depleted in napthalenes and less than 10,000 mg/kg.	Diluted bitumens do not contain higher concentrations of either BTEX or TPAH than many conventional crude oils (Lee et al. 2015). Diluted bitumens contain the same suite of PAHs as conventional crude oils, but at different relative concentrations due to the highly weathered nature of the bitumen component, and the modifying effect of the diluent. These details are further discussed in section 7.1.2. Compared to endothermic vertebrates (i.e., birds and mammals), acute effects on amphibian and reptiles are more likely to occur through chemical toxicity of oil than physical effects of oiling. Lower proportions of toxic constituents would result in reduced potential effects on amphibians and reptiles.

Table 7-37 Biological Receptor: Amphibians and Reptiles

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—persistence	Light crude oils typically contain only small proportions of higher molecular weight components, such as resins and asphaltenes. Light crude oils generally biodegrade readily.	Medium crude oils contain variable proportions of resins and asphaltenes. Asphaltenes would be removed from synthetic medium crudes during processing of bitumen.	Heavy conventional crude oils and diluted bitumens typically contain higher proportions of resins and asphaltenes, which tend to resist biodegradation.	In general, heavy conventional crude oils and diluted bitumens would be expected to biodegrade less rapidly than light or medium crude oils. However, any oil can be persistent if deposited in an environment where there is little or no available oxygen. Increased persistence in the environment would result in a similar increase in potential exposure duration by amphibians and reptiles.

Table 7-38 Biological Receptor: Amphibians and Reptiles

Environmental Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Habitat type	Light crude oil will spread rapidly due to its low viscosity, potentially resulting in effects over a larger area in lakes and wide rivers.	Medium crude oil has low viscosity, although viscosity increases at lower temperatures, and will behave similarly to light crude oils.	Heavy crude oils have high viscosity. Diluted bitumens also have high viscosity (although reduced while fresh due to the effect of the diluent), potentially resulting in effects over a smaller area in lakes and wide rivers, due to the oil's resistance to spreading in these habitats.	Low viscosity oils will spread more rapidly, and to thinner slicks, than high-viscosity oils. As a result, low viscosity oils have a higher potential to affect a larger area of habitat, particularly open-water habitats such as lakes and wide rivers, than higher viscosity oils. At the same time, higher viscosity oils will tend to form thicker slicks than low viscosity oils. This could result in a smaller area of higher impact to habitat suitability for amphibians and reptiles compared from heavy oils compared to light oils.
Season	Light oils remain fluid at low temperature and retain the potential to spread rapidly during the winter. Light oils may penetrate cracks in ice or close to shore, allowing the oil to get beneath the ice and spread downstream. In summer, light crude oils would also flow readily and spread rapidly, having the potential to contact larger numbers of amphibians and reptiles than heavier, more viscous oils.	Medium oils are slightly more viscous than light oils, and would also tend to flow readily under winter conditions. Medium crude oils would tend to flow readily and spread rapidly under summer conditions	Heavy oils become much more viscous at low temperatures, and as they weather. Heavy oils and diluted bitumens would have more resistance to flowing or penetrating cracks in ice to reach the water surface than would be the case for light or medium crude oils. During the summer, diluted bitumens would flow readily and spread rapidly while fresh. Weathering in the first 24 to 48 hours would result in increasing viscosity and density, limiting further spreading of the oil on the water surface.	Season affects both the behavior of oil in the environment, and the types and abundance of amphibians and reptiles that could be exposed. Most amphibians and reptiles become dormant during the winter and would only be exposed to oil during the open water period when they are active. This would limit the potential for direct exposure during the winter period, though indirect effects to food and habitat may still occur from a winter release.

Table 7-38 Biological Receptor: Amphibians and Reptiles

Environmental Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Weather conditions—rainfall and water levels	Periods of high rainfall and high water levels could transport released crude oil into riparian areas, in addition to potentially increasing downstream transport distances. This would affect all crude oil types. If crude oil is transported into riparian areas, then this could increase the potential for more terrestrial species (toads and snakes) to be exposed, as well as have potential effects to nests of reptiles that burrow into riparian substrates to build their nests (e.g., turtles).			
Weather conditions—temperature	Temperature would have limited implications for effects oil on amphibians and reptiles due to their ectothermic nature (e.g., cold-blooded), which prevents these species from becoming hypothermic. Temperature would have effects on the behavior of oil in the environment (see oil characteristics table above).			
Slope	Lakes have negligible slope, and therefore the short-term distribution of crude oil on the water surface may be determined primarily by wind. Streams and rivers have slope, which determines the downstream water flow velocity, as well as influencing the turbulence of that flow. Slope therefore helps to determine the downstream transport distance for spilled oil before emergency response can be effectively applied. This can affect the types of habitat that the spilled oil could affect, as well as the numbers and types of amphibians and reptiles.			

7.1.3.6 Birds

7.1.3.6.1 Description

There are hundreds of species of birds in North America, many of which are aquatic or semi-aquatic, using wetlands, lakes, rivers, or streams as components of their habitats. The dependence of birds on aquatic habitat ranges from facultative (e.g., use of aerial habitat over water by swallows when foraging for emerging aquatic invertebrates) to obligate (e.g., use of aquatic and shoreline habitat by divers and some ducks for foraging, rearing young, and constructing nests along shorelines or on floating vegetation). This receptor group—Birds—focuses primarily on waterbirds (e.g., gulls, terns, loons), waterfowl (e.g., ducks, geese, swans), and shorebirds (e.g., sandpipers, plovers, herons, cranes) that are often intimately associated with aquatic environments, as these are the most vulnerable to releases of hydrocarbons (Albers 2003). However, members of other bird groups, such as raptors and songbirds, are also considered in this environmental effects assessment.

Birds have dietary preferences that range from piscivory (fish-eating species such as osprey, loons, mergansers) and insectivory (insect-eating species such as swallows, lesser scaup and spotted sandpiper) to omnivory (species that consume a variety of foods such as mallard) and herbivory (species that consume primarily vegetation such as Canada goose). Nesting habits of aquatic birds range from stick nests in trees located close to water (e.g., eagles, osprey, and herons), and ground-nesting species that may build nests in adjacent uplands or close to shorelines (e.g., spotted sandpiper, and lesser scaup), to species that build nests on floating vegetation as a predator avoidance mechanism, such as the horned grebe.

Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species which leave their summer (and often breeding) habitat in the fall for wintering areas farther south, where they can find open-water habitat. Timing of migration varies among species, and is usually a function of migratory distance. Long-distance migrants depart earlier and arrive later, with more predictable migration timing, whereas short-distance migrants will arrive as soon as aquatic environments begin to open in the spring and depart only when lakes and rivers freeze in the fall. However, some aquatic birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available.

There is only one federally-listed bird in this receptor group (the piping plover, *Charadrius melodus*, Endangered, USFWS 2016) that is likely to occur in the study area (i.e., Minnesota). In addition, there are several receptor group species listed under Minnesota's Endangered Species Statutes (MN DNR 2013). These include:

- Horned grebe (*Podiceps auritus*) — Endangered
- King rail (*Rallus elegans*) — Endangered
- Wilson's phalarope (*Phalaropus tricolor*) — Threatened
- Common tern (*Sterna hirundo*) — Threatened
- Yellow rail (*Coturnicops noveboracensis*) — Special concern

- Trumpeter swan (*Cygnus buccinator)* Special concern
- Common gallinule (*Gallinula galeata*) Special concern
- Franklin's gull (*Leucophaeus pipixcan*) Special concern
- Marbled godwit (*Limosa fedoa*) Special concern
- Louisiana waterthrush (*Parkesia motacilla*) Special concern
- American white pelican (*Pelecanus erythrorhynchos*) Special concern
- Forster's tern (*Sterna forsteri*) Special concern

7.1.3.6.2 Observed Effects

A review of hydrocarbon releases from pipelines, as well as one example each for a rail car release and a release from a storage tank, provide an overview of observed effects of oil releases on birds in aquatic environments (e.g., river, lakes and wetlands) similar to those that could be encountered in Minnesota. This review is not exhaustive, but provides a range of observed effects of a variety of oil types on birds, under different environmental conditions. The case studies will provide an empirical basis from which the likely effects of oil releases on aquatic birds can be predicted, with consideration of the modifying effects of oil type, and environmental factors.

> ***Ashland Petroleum****: On January 2, 1988, a 40 year old storage tank collapsed at the Ashland Oil Facility in West Elizabeth, Pennsylvania. The tank collapse released approximately 90,500 barrels of diesel fuel, of which 23,800 barrels flowed into the Monongahela River 27 miles south of Pittsburgh, Pennsylvania. As the release moved downstream, water supplies were contaminated, resulting in the disruption of water services to riverside cities in Pennsylvania, Ohio, and West Virginia. As of January 7, 1988, only 1,900 barrels of product had been recovered (NOAA 1992). The effort to recover the oil was hindered by dams and locks along the Ohio River, ice cover, emulsification of the oil, and dispersion of the oil into the water. The Pennsylvania Game Commission assisted by volunteers set up bird cleaning programs and monitored for oiled wildlife, though efforts were hampered by weather conditions and by partial ice cover that resulted in rescue workers not being able to access areas where birds were concentrated. Waterbird and waterfowl mortality estimates ranged from 2,000 to 4,000 birds, including ducks, loons, cormorants and geese among others (Miklaucic and Saseen 1989). The high mortality was likely due to the response limitations arising from environmental conditions which prevented crews from deterring birds from oiled sites and rescuing birds that had remained in open water areas of the river (Miklaucic and Saseen 1989).*

> ***Exxon Bayway****: On January 2, 1990, an underwater pipeline released approximately 13,500 barrels of No. 2 heating oil into the Arthur Kill waterway at the mouth of Morse Creek between New Jersey and Staten Island, New York (NOAA 1992). Initial response efforts focused on containment of the release and removal of the larger masses of oil. Concentrations of floating oil and mousse in the open water, primarily between Howland Hook and Fresh Kills, were collected by self-propelled skimmers. Oil concentrated and stranded above the berm on the beaches from Cedar Point to Rossville, as well as in other natural areas. Factors resulting in the dispersal of oil beyond the berm were not*

reported, though it could have been due to tidal and wave action. Environmentally sensitive areas were protected with boom and skimmers that collected the larger masses of free-floating oil. Even though the incident occurred in January, the environment was a coastal marsh system that allows many species of aquatic birds to overwinter as a result of the open water maintained by tidal action and salt water. A total of 841 birds were reported oiled, with 691 fatalities. The most common groups were waterfowl and gulls (45% of the oiled birds each) (NOAA 1992; French McCay and Rowe 2004).

***Lakehead**: On March 3, 1991, a Lakehead Pipeline Company, Inc. owned pipeline ruptured and released over 40,000 barrels of crude oil (NOAA 1992) approximately two miles north of Grand Rapids, Minnesota. Some of the oil spread onto the 18-inch thick ice sheets on the Prairie River. Oil formed into 8 inch deep pools on top of the ice in the middle of the river and was also present under the ice. Vacuum trucks were used by clean-up personnel to remove the oil from the surface of the ice. Workers used squeegees to push the oil along the ice to a removal location. Booms were used on the river by cutting a slot through the ice cover with chainsaws. Ice that had been permeated with oil was chopped into blocks small enough to be carried away to a separate part of the river. Clean-up personnel sprayed the ice blocks with hot water to wash out the oil, which was then recovered with skimmers. Blocks that were only slightly contaminated were moved to lined holding tanks and broken up. The crushed ice was then allowed to melt to recover residual oil. There were no specific reports of oiled birds, or of the death of any birds; effects to fish and wildlife were reported as minimal by the MN DNR (Telegraph Herald 1991), likely due to ice-covered conditions at the time of the release.*

***OSSA II**: On January 30, 2000, an estimated 29,000 barrels of mixed heavy crude oil and diluent (combined density of approximately 0.8 g/mL) were released from the Transredes S.A operated OSSA II pipeline at the Rio Desaguadero river crossing in Bolivia as the river was rising to peak flood conditions (Lee et al. 2001, 2002; Owens and Henshaw 2002). Due to the very high river flow and water velocity conditions, and perhaps also due to the low viscosity of the oil which would allow it to become dispersed into the water as fine droplets, oil was found up to 230 miles downstream from the release location. For the most part, the surface oil was deposited onto river banks in strips, generally 3 to 6 ft wide and up to 0.5 to 1 inch thick. Many sections of river bank had a horizontal line of oil (a bathtub ring) where the oil was stranded, indicating the water level at the time (Owens and Henshaw 2002). The response effort included more than 3,600 people who recovered the oil within three months. Wasson et al. (2000; in Owens and Henshaw 2002) reported that few birds (in the order of tens; species not reported) were initially oiled by the release; observers did not detect additional birds in the weeks and months following the release, despite the high numbers of birds in the area.*

***Pine River**: On August 1, 2000, a Pembina Pipeline Corp. pipeline failure released approximately 6,200 barrels of light crude oil, of which an estimated 2,800 barrels entered*

the Pine River 70 miles upstream of Chetwynd, British Columbia (BC MOE 2000a). An estimated 300 to 710 barrels remained unaccounted for following the clean-up and remediation (Goldberg 2011). Most of the oil unaccounted for was considered likely to be entrained in sediment or debris in the river channel. Response measures included placing two containment systems, one approximately 14 miles downstream and a second approximately 19 miles downstream (BC MOE 2000c). The river was flowing at a low stage at the time of the release (approximately 5,680 ft^3/s measured at a station 100 miles downstream compared to flow rates above 31,880 ft^3/s during late spring and early summer) (Bustard and Miles 2011). The Pine River has a gradient of approximately 0.225% in the first 25 miles downstream from the release location, decreasing to 0.1% farther downstream (Bustard and Miles 2011).

A golden eagle and a hooded merganser were reportedly affected by the release. The eagle recovered, but the merganser was euthanized. No other birds were found by government staff or clean-up crews (BC MOE 2000b).

***Wabamun Lake**: On August 3, 2005, a Canadian National freight train derailed near the Village of Whitewood Sands, Alberta, releasing approximately 4,500 barrels of Bunker C fuel oil (Heavy Fuel Oil 7102; Hollebone et al. 2011) and 550 barrels of pole treating oil. An estimated 950 barrels of the Bunker C oil entered Wabamun Lake where it formed a thick black slick approximately 0.5 in. thick (Wernick et al. 2009). The heavy Bunker C product formed several types of aggregates including tar balls, larger tar "logs", submerged sheets, large lumps, tar balls that sometimes reformed into oil slicks, and a "slurry" composed of finely divided organic matter and small oil droplets (Fingas et al. 2006; Hollebone et al. 2011). The oil exhibited a variety of behaviors including submergence, neutral buoyancy, and resurfacing as a result of contacting and taking up foreign matter (such as mineral particles and organic debris) on its path to the lake (Fingas et al. 2006). No dispersion of oil in water was observed in the lake, and no mousse formation was reported in the three years following the release (Hollebone et al. 2011). Overall, the water in the open water area of the lake was reported to be not contaminated with released hydrocarbons or associated metals (Anderson 2006). This is consistent with the very low concentration of relatively water-soluble components (such as BTEX) in the released oil, and the relatively low water solubility of this heavy oil. Similarly, sediments beneath the open water portions of Wabamun Lake were reported not to have been contaminated with petroleum hydrocarbons and were considered to be of similar quality to concentrations measured in 2002 or shortly before the release (Anderson 2006).*

Clean-up activities included cutting of the vegetation and vacuum removal of submerged tar balls entrained in the reed bed detritus (Wernick et al. 2009). A two-year study was conducted to assess regrowth. The study found that exposure to the oil, which was released late in the growing season, did not cause large-scale changes to these emergent plant communities (Wernick et al. 2009). Physical factors such as clean-up activities and vegetation management appeared to be responsible for reduced

regrowth of vegetation observed at some locations (Wernick et al. 2009; Thormann and Bayley 2008).

Wabamun Lake is one of nine lakes in Alberta found to support western grebe colonies in 2006 (Kemper et al. 2008). The Alberta population is estimated at between 10,000 and 11,000 birds, representing approximately 10% of the North American population. The Wabamun Lake colony contains between 100 and 500 nests and is considered to be regionally important (Kemper et al. 2008). During 2001–2005, western grebes at Wabamun Lake nested in one main colony (Rich's Point), and the lowest reported number of nests was 243 in 2005. The release occurred after completion of nesting that year, killing an estimated 333 western grebes (about 69% of the adult population). A wildlife recovery center was set up immediately after the release. More than 530 oiled birds were recovered within five days after the release. Of those, 156 were either dead when recovered, or euthanized thereafter (TSBC 2007). The following summer, the resurfacing of submerged oil resulted in the oiling of additional waterfowl, though specific estimates were not provided (TSBC 2007).

In 2006, western grebes returned to nest at Rich's Point, and in addition, formed a second colony at the Ascot Beach reed bed. Together, the two sites contained 456 nests in 2006 and over 1,000 nesting adults (Kemper et al. 2008; Wollis and Stratmoen 2010). Populations at Wabamun lake followed similar trends pre- and post-release to those of the regional population (Wollis and Stratmoen 2010; AESRD and ACA 2013), suggesting that the release did not cause substantial long-term changes at this location.

***Glenavon**: On April 15, 2007, a release occurred on the Enbridge Line 3 pipeline approximately 1 mile downstream of the Glenavon pump station near Glenavon, Saskatchewan. The rupture released approximately 6,200 barrels of heavy crude oil and affected approximately five acres of a wetland on farmland (TSBC 2008a; SLR Consulting 2008a). Within two days of the release, approximately half of the crude oil had been recovered (Canada.com 2007a). The site was monitored for one week for exposure of wildlife to oil, and wetlands within 0.6 miles (1 km) were surveyed for any wildlife that may have been oiled initially and moved from the release site. Of the five birds affected (four Canada geese and one savannah sparrow), two Canada geese were euthanized, one Canada goose (which was able to fly) eluded capture and disappeared from the area, and one Canada goose and savannah sparrow were captured and transported to the Small Animal Clinic at the Western College of Veterinary Medicine. The Canada goose was successfully cleaned and considered for release, though the final action was unknown. The savannah sparrow died during clean-up (SLR Consulting 2008a). Response activities included the use of wildlife deterrents and fencing around the perimeter of the slough. The small number of birds oiled by the release was attributed to the release occurring at night when semi-aquatic birds are less likely to be active (SLR Consulting 2008a), and to mobilizing of a rapid response to avoid further exposure of birds.*

***Marshall**: On July 25, 2010, Enbridge's Line 6B pipeline experienced a release in a wetland near Marshall, Michigan. Approximately 20,000 barrels of heavy crude oil containing diluted bitumen were released over a period of about 17 hours. The pipeline contained two different batches of crude oil at the time of the release (NTSB 2012a). It is estimated that the released oil consisted of approximately 77% CLWB diluted bitumen and 23% Western Canadian Select, as well as diluted bitumen (Enbridge 2013a). Of this, approximately 8,000 barrels reached Talmadge Creek and the Kalamazoo River (Enbridge 2013a). During clean-up and monitoring, 52 birds were either found dead or died during attempted rehabilitation (USFWS et al. 2015a). In addition, 144 oiled birds were captured, successfully rehabilitated and released. There were approximately 140 additional birds observed oiled, but never captured. The primary species were Canada goose (75%), mallard (9%), and great blue heron (5%) (USFWS et al. 2015a). Of the birds rehabilitated and released, 127 were banded including 109 Canada geese. Between 2010 and 2015, 39 of those bands were recovered from hunters (unpublished banding data), indicating that birds survived post-release and were able to complete migration and dispersal.*

***Rainbow**: On April 28, 2011, a pipeline owned by Plains Midstream Canada released approximately 28,300 barrels of sweet crude oil into a muskeg/stagnant water area near the community of Little Buffalo in the Peace River region of Alberta. The release occurred on a hillside, and the oil flowed a half mile down the pipeline ROW and pooled in a low-lying area containing abandoned beaver ponds. The release encompassed an area of approximately 20 acres (ERCB 2013). As part of the response, wildlife mitigation measures, which included fencing and various deterrents, were implemented (ERCB 2013). Despite these measures 79 birds were reported to have died by November 2012, with most of the deaths occurring shortly after the release (i.e. within a few months). Bird species included in the reported fatalities were a mixture of approximately one-third waterfowl and two-thirds shorebirds and passerines; the particular species affected were not reported (ERCB 2013).*

***2011 Yellowstone River**: On July 1, 2011, flood conditions in the Yellowstone River resulted in a release from the ExxonMobil Silvertip Pipeline carrying medium sour crude oil near Laurel, Montana. Riverbed erosion exposed the 12-in. pipeline beneath the crossing, and debris caught on the washed-out pipeline causing stress, resulting in a clean break (i.e., a full bore rupture). The failure was detected at the pipeline control center and the line was shut down within 10 minutes (USDOT 2012). Approximately 1,500 barrels of crude oil was released into the Yellowstone River (USDOT 2012). The affected reach of the Yellowstone River has an average gradient of 0.17%. Crude oil affected primarily shorelines and banks immediately downstream of the release site (MT DEQ 2015b). According to the USEPA (2011), at least 19 oiled animals were confirmed to have been visibly oiled, including one bald eagle. Ten wildlife fatalities were reported, though no information on species or fate was provided (USEPA 2011).*

***Red Deer River**: On June 7, 2012 a Plains Midstream Canada ULC (Plains) pipeline released approximately 2,900 barrels of light crude oil into the Red Deer River downstream of Sundre, Alberta as a result of high water levels in the river that exposed the pipeline and caused structural damage (AER 2014). The migration of surface oil was stopped by booms placed at Gleniffer Lake, but dissolved hydrocarbons continued to move downstream. This resulted in potential for both toxicological and physical effects upstream of the booms, but limited potential for physical effects downstream (Teichreb 2014). As a result of the release, one Canada goose and one American crow were oiled; the animals were brought to the Medicine River Wildlife Centre where they were cleaned and treated (Derworiz 2012). Officials with Alberta Environment indicated that impacts to wildlife were minimal (Derworiz 2012).*

***Line 37**: On June 22, 2013, unusually heavy rains caused ground movement that compromised the integrity of the Enbridge Line 37 pipeline approximately 1 mile north of the terminal in Cheecham, Alberta. The resulting failure released approximately 1,300 barrels of synthetic light crude oil underground with some oil seeping to the surface where it flowed overland entering a wetland and unnamed lake (Enbridge 2013c). Initial clean-up and remediation recovered 93% of the crude oil with the remaining oil found in soils and the fen. Effects on semi-aquatic birds included two blue-winged teal found dead as a result of the release. A third teal was observed to be oiled, but may have been oiled post-mortem after predation by a fox (Focus Wildlife Canada 2013). The small number of reported oiled birds was potentially due to the low density of waterfowl and other aquatic birds in the area, but may also have been influenced by the short time required to implement spill response and mitigation measures.*

***Mid Valley**: On October 13, 2014, a Sunoco pipeline release occurred near Mooringsport, Louisiana, resulting in approximately 4,500 barrels of sweet crude oil entering the Miller branch of the Tete Bayou, which feeds into Caddo Lake. Although containment booms prevented the oil from entering Caddo Lake, approximately 10 miles of the creek were affected. Media reported that 486 dead animals were collected and 47 were cleaned and released (Wellborn 2014a). Most of the animals were crawfish and amphibians, but numbers and species were not provided. One wood duck was reportedly oiled, cleaned and released (Welborn 2014b), but this area would likely have been inhabited by shorebirds, wading birds, waterfowl, and other marsh birds.*

***Yellowstone River**: On January 17, 2015, a Bridger Pipeline LLC pipeline released approximately 715 barrels of Bakken crude oil (estimates ranged from 300 to 1,200 barrels) into the Yellowstone River approximately 5 miles upstream of Glendive, Montana (MT DEQ 2015b). The pipeline breach occurred where the pipeline crossed under the river. Winter conditions resulted in extensive ice cover, but aerial patrols discovered oil as far as 25 miles downstream of Glendive (The Guardian 2015). Booms were deployed on the ice and in areas of open water downstream to collect oil from the surface (Hirji 2015) but winter conditions combined with thawing resulted in unsafe working conditions and*

only a limited amount of oil (approximately 60 barrels, MT DEQ 2015a) was recovered from the river. There were no reports of oiled wildlife (including birds) or dead fish (Stuart 2015). The Montana Departments of Natural Resources and Conservation and Fish, Wildlife and Parks expressed concern that the most important source of damage to the riverine system was the physical damage caused by response crews and equipment during clean-up operations.

7.1.3.6.3 Expected Effects of Released Oils

The case studies in the foregoing section provide the opportunity to highlight key differences between oil releases to inland waters to those in marine environments.

The first consideration is the environment in which the releases occur. For marine releases, oil can spread and be transported by wind and currents with the potential to affect a very large area. In contrast, inland releases are almost always constrained. Releases to wetlands and small lakes (e.g., the Line 37 release) provide natural traps limiting the spread of oil and preventing damage to downstream habitats. Even releases to rivers are constrained to the river channel. River banks provide substrates where oil can strand and be retained, thereby limiting downstream migration and facilitating emergency response measures.

Secondly, the effects of an inland oil release, while potentially having severe local effects to birds, are likely to have only minor regional or population level effects unless they occur in sites where a high proportion of a species' population congregates. This is due to the redundancy provided by unaffected habitat upstream, downstream, or in unaffected nearby watersheds. As a result, only a small portion of a regional population may be exposed to oil after an inland oil release. Exceptions could occur if releases affect areas where birds are concentrated in an isolated area of open water during winter conditions (e.g., the Ashland release) or where there are breeding concentrations of birds (e.g., the Wabamun Lake release). Locations of importance to regional or continental populations of birds, such as Western Hemisphere Shorebird Reserve Network Sites or Important Bird Areas, are generally well known and potential effects of releases predicted. Thus, except in unusual circumstances, the environmental effects of oil releases on birds in inland habitats tend to be limited to small numbers of individuals than for marine oil releases. Large releases of crude oil to the marine environment have the potential to affect large numbers of individuals and species (as was the case for the Exxon Valdez oil release; Weins et al. 2013).

Hydrocarbon releases can harm birds through physical effects, acute and chronic toxicological effects, and through changes in habitat (Albers 2003; Malcolm and Shore 2003). The environmental effects of an oil release on aquatic and semi-aquatic birds will therefore depend upon the amount of oil released, the environment that the oil is released into, and the numbers and types of aquatic and semi-aquatic birds that are exposed to the oil. Secondarily, oil spill response measures will help to limit the spread of released oil and, in doing so, will reduce the potential exposure of birds. In addition, capture and rehabilitation of oiled birds may help to reduce mortality.

Detecting dead birds following a hydrocarbon release in the aquatic environment is challenging, and is known to under-represent the true number of fatalities associated with a hydrocarbon release. For example, Byrd et al. (2009) estimated that only 14.6% of carcasses along coastal (marine) beaches remained after 24 hours due to scavenging. Moreover, searchers averaged a 40% detection rate of carcasses known to be present after a single pass, and a cumulative increase to 70% detection following a second pass. Comparable statistics for inland water bodies are not available.

The following sections provide further insight into the role of oil type and environmental factors on the environmental effects of released oil on aquatic and semi-aquatic birds.

7.1.3.6.3.1 Direct Physical Effects of Oil on Birds

The most easily observed and reported effect of a hydrocarbon release on birds is physical oiling of plumage. Feathers provide aquatic birds with buoyancy and insulation. Oiling impairs both of these properties, and the added weight may affect a bird's ability to fly, affecting foraging, migration, and predator avoidance. Also, oiling often results in death from hypothermia or drowning of birds that are obligate users of aquatic habitat (Vermeer and Vermeer 1975; Jenssen 1994), particularly in cold-water environments. Smaller birds are likely to succumb to physical oiling at a faster rate than larger birds, as the surface area of smaller organisms is larger in proportion to their body mass. Body size effects would also result in greater impairment of small birds, which would require proportionally greater effort to fly with partial oiling. Lower ambient temperature will amplify the physiological effects of reduced insulation in organisms. As noted above, heat loss will also be much greater for a bird immersed in cold water than for a bird immersed in air at the same temperature (Knopper et al. 2016). A higher rate of heat loss will lead to faster onset of hypothermia and potentially death in oiled birds. A partially oiled bird might be susceptible to hypothermia if exposed to cold air or water, while the same bird might survive partial oiling if exposed to moderate or warm temperatures (Knopper et al. 2016). However, for birds such as gulls, shorebirds, and waders that have sufficient behavioral plasticity to avoid immersion in cold water when oiled, long-term survival and an ability to self-clean and recover from light to moderate oiling has been reported (Camphuysen 2011).

The effect of oil type on oiling of birds has not been directly studied, but evidence from marine studies would suggest that any oil type can be harmful. The NRDAM/CME (French et al. 1996) bases the assessment of harm to marine birds on slick thickness, with predictions of bird mortality on a threshold slick thickness of 10 µm. As heavier crude oils have higher adhesion than lighter crude oils (NAS 2016), it would be more difficult for individuals to remove heavier crude oil from feathers through preening, and could also result in greater ingestion of hydrocarbons by birds than for lighter crude oils. While it is reasonable to conclude that light oils could spread to very thin sheens (less likely to be harmful to aquatic birds) than more viscous heavy oils, it is also reasonable to conclude that a release of light oil could spread to affect a larger area and therefore affect more birds than a similar sized release of heavy oil. The exact outcome of exposure of birds to oil will depend on climate and other influences on both oil dispersion and the distribution of birds, as well as oil type.

7.1.3.6.3.2 Direct Toxicological Effects of Oil on Birds

Acute toxic effects are less common in birds and other terrestrial vertebrates that can escape from a region where oil has been released into the environment. Acute and chronic effects on birds of hydrocarbon exposure through ingestion or inhalation pathways are generally considered less serious than the physical effects of external oiling (Albers 2003). Acute toxicity of ingested hydrocarbons or inhaled hydrocarbon vapor in birds is generally the result of liver failure, narcosis and other biochemical responses (Albers 2003, 2006). Low molecular weight hydrocarbons can result in acute effects shortly after an oil release when they are in sufficiently high concentrations at the site of release (and in the ingested oil), prior to being diluted in the environment or evaporating into the atmosphere (weathering).

Direct toxicological effects on birds of hydrocarbons released to the environment are generally less significant for adult birds than physical effects described previously. Studies, generally with ducks, have shown that naturally weathered Exxon Valdez crude oil presented little potential for toxicity to wildlife species from oral ingestion (Stubblefield et al. 1995a, b). In the short term, birds are most likely to ingest hydrocarbons directly as a result of preening oiled feathers with their bills, but also through ingestion of food and incidental ingestion of sediment (Albers 2003). Ingestion of oil is seldom directly lethal, but it can cause many debilitating sublethal effects that promote death from other causes, including starvation, disease, and predation (Albers 2003, 2006). Effects include gastrointestinal irritation, pneumonia, dehydration, red blood cell damage, impaired osmoregulation, immune system suppression, hormonal imbalance, inhibited reproduction, retarded growth, and abnormal parental behavior (Albers 2003, 2006). Therefore, birds that survive external oiling without succumbing to hypothermia may be at secondary risk of death due to ingesting a quantity and mixture of hydrocarbon compounds, which can then result in multiple additional effects. Birds that survive external oil exposure may subsequently be indirectly exposed to hydrocarbons (of which the polycyclic aromatic hydrocarbons or PAHs are of greatest concern) through contaminated food, and incidental ingestion of contaminated sediment, soil or water.

During the breeding season, birds carrying hydrocarbons on their feathers are also at risk of transferring oil to their eggs. Studies examining the effect of eggshell oiling found that small quantities of oil can cause embryonic death. Effects were more pronounced for light crude oils, as they contain higher proportions of BTEX and 2-ring PAHs (Hoffman 1990), which are capable of penetrating through the eggshell and egg membrane. This is consistent with results of a study by Szaro et al. (1980) showing that weathered oils were slightly less toxic to mallard eggs than fresh oils. However, toxicity was dose-dependent through the range of 1 and 50 µL of oil per egg (Szaro et al. 1980).

7.1.3.6.3.3 Indirect Effects of Oil on Birds

Indirect effects of hydrocarbon releases to birds occur through effects to habitat or food quality or availability (Wiens et al. 2013). Because aquatic birds inhabiting inland freshwater environments are typically only present during the open-water season, their habitat requirements are seasonal during the migration and breeding period. The magnitude of effects

on breeding habitat of semi-aquatic bird species depends on their nesting behavior. Species such as gulls or terns that nest in colonies on islands, or in habitat that may be limiting (e.g., grebes nesting in reed beds) may have fewer options when seeking alternative nesting locations following a disturbance than species with greater plasticity in habitat requirements (e.g., spotted sandpiper). Where oil becomes entrained in riparian or wetland vegetation, remediation activities that include vegetation clearing could affect nesting or roosting habitat of aquatic and semi-aquatic birds (see Wabamun Lake case study).

Foraging habitat loss depends on a species foraging behavior and the fate of released hydrocarbons in the environment. Hydrocarbons collecting along shorelines and riparian bank areas would primarily affect shorebirds. Oil entrained in emergent or submerged vegetation in wetlands, deadwater areas of rivers, and shallow portions of lakes would affect waterfowl, waterbirds and wading birds (e.g., herons). However, as birds are capable of dispersing to unaffected areas to forage, effects of hydrocarbon releases would be limited to the aquatic system in which the release occurred. At a regional level, population effects would not likely be observed (Albers 2003). Indirect effects could also result from changes in food quality or abundance. Effects of hydrocarbon releases on aquatic invertebrates or fish could temporarily reduce prey availability or quality for birds.

7.1.3.6.4 Summary of Inland Oil Release Effects on Birds

Table 7-39 and Table 7-40 provide a summary of the expected environmental effects of oil releases to aquatic and semi-aquatic birds in inland environments. Table 7-39 considers the effects of specific oil characteristics or oil type on the expected types and scope of environmental effects. Table 7-40 considers the effects of environmental characteristics on the expected types and scope of environmental effects.

Table 7-39 Biological Receptor: Semi-aquatic Birds

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—buoyancy	Light crude oils typically have a low relatively density (0.78-0.88 g/mL, Dupuis and Ucan-Marin 2015) and are buoyant in freshwater aquatic environments.	Medium crude oils typically have an intermediate density compared to light and heavy crudes, and are buoyant in freshwater aquatic environments (Dupuis and Ucan-Marin 2015).	Heavy conventional crude oils can have density ranging of 0.88 to 1.00 g/mL, while diluted bitumen will have density less than 0.94 g/mL (Dupuis and Ucan-Marin 2015).	While raw bitumen has a higher density than water, diluted bitumen is less dense and limited evaporative mass loss at environmentally-relevant temperatures suggests that weathered dilbit will remain afloat as it will retain sufficient diluent to maintain a lower density ((Lee et al. 2015; see also Section 7.1.2). Recovery of released oil is facilitated if the oil floats on the surface of the water.
Oil properties—viscosity	Light crudes will spread rapidly on water because of their low viscosity (1 to 5 mPa•s, NAS 2016).	Medium crudes have an intermediate viscosity (8 to 112 mPa•s, NAS 2016).	Heavy crudes (820 to 475,000 mPa•s) and diluted bitumens (270 to 50,000 mPa•s) weather to high viscosity (NAS 2016).	Viscosity is a function of oil chemistry. Diluted bitumens tend to display a more rapid increase in viscosity due to weathering than conventional heavy crude oils as a result of the rapid initial evaporation of some of the diluent. Oil having low viscosity will rapidly spread across the water surface forming a thin and relatively uniform slick. More viscous oils will spread more slowly and may exhibit thicker but patchier slicks with associated sheens.
Oil properties—adhesion	Light crudes have low adhesion and viscosity (NAS 2016) and can be expected to penetrate the feather layer to contact skin.	Medium crudes have an intermediate adhesion and viscosity (NAS 2016). Medium crude oils also readily penetrate the feather layer to contact skin.	Heavy crudes, particularly diluted bitumens, are highly adhesive and more viscous than light and medium crude oils. Fresh diluted bitumens have relatively low viscosity, and would penetrate feathers. However, weathered heavy crudes may tend to stick to the surface of feathers without penetrating to contact the skin.	Properties of adhesion and viscosity may change the way that crude oil interacts with feathers. Light oils may more readily penetrate feathers and destroy insulation; heavy oils, particularly when weathered, may tend to adhere in a thick layer to the feather surface without immediately penetrating to the skin surface. This results in more difficult cleaning and removal of oils from feathers, greater added weight and extended duration of physical effects.
Oil chemistry—	Light crude oils	Medium crude oils	Levels of BTEX and other relatively	Diluted bitumens do not contain higher

Table 7-39 Biological Receptor: Semi-aquatic Birds

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
toxic constituents	often contain high levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, depending on the oil type, but can be high (>10,000 mg/kg) in Bakken oils.	often contain moderate levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, but can exceed 10,000 mg/kg.	water soluble constituents are variable: generally low in heavy conventional oils, but variable in diluted bitumens depending upon the nature of the diluent. Levels of TPAH are variable, but typically depleted in napthalenes and less than 10,000 mg/kg.	concentrations of either BTEX or TPAH than many conventional crude oils (Dupuis and Unca-Marin 2015; Lee et al. 2015). The characteristics of diluted bitumen are further discussed in Section 7.1.2. Acute effects on bird populations are generally caused by physical oiling, not related to the BTEX content of the oil. Chronic effects on birds of released crude oil, if any, are likely due to dietary TPAH exposure. Diluted bitumens contain the same suite of PAHs as conventional crude oils, but at different relative concentrations due to the highly weathered nature of the bitumen component, and the modifying effect of the diluent.
Oil properties—persistence	Light crude oils typically contain only small proportions of higher molecular weight components, such as resins and asphaltenes. Light crude oils generally biodegrade readily.	Medium crude oils contain variable proportions of resins and asphaltenes. Asphaltenes would be removed from synthetic medium crudes during processing of bitumen.	Heavy conventional crude oils and diluted bitumens typically contain higher proportions of resins and asphaltenes, which tend to resist biodegradation.	In general, heavy conventional crude oils and diluted bitumens would be expected to biodegrade less rapidly than light or medium crude oils. However, any oil can be persistent if deposited in an environment where there is little or no available oxygen.

Table 7-40 Biological Receptor: Semi-Aquatic Birds

Environmental Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Habitat type	Light crude oil will spread rapidly due to its low viscosity, potentially resulting in effects over a larger area in lakes and wide rivers.	Medium crude oil has low viscosity, although viscosity increases at lower temperatures, and will behave similarly to light crude oils.	Heavy crude oils have high viscosity. Diluted bitumens also have high viscosity (although reduced while fresh due to the effect of the diluent), potentially resulting in effects over a smaller area in lakes and wide rivers, due to the oil's resistance to spreading in these habitats.	Low viscosity oils will spread more rapidly, and to thinner slicks, than high-viscosity oils. As a result, low viscosity oils have a higher potential to affect a larger area of habitat, particularly open-water habitats such as lakes and wide rivers, than higher viscosity oils. At the same time, higher viscosity oils will tend to form thicker slicks than low viscosity oils. This could lead to a contrast of "more habitat and birds oiled less heavily" (lighter oils) as compared to less habitat and fewer birds oiled more heavily (heavier oils) for a spill of the same magnitude.
Season	Light oils remain fluid at low temperature and retain the potential to spread rapidly during the winter. Light oils may penetrate cracks in ice or close to shore, allowing the oil to get beneath the ice and spread downstream. In summer, light crude oils would also flow readily and spread rapidly, having the potential to contact larger numbers of birds than heavier, more viscous oils.	Medium oils are slightly more viscous than light oils, and would also tend to flow readily under winter conditions. Medium crude oils would tend to flow readily and spread rapidly under summer conditions.	Heavy oils become much more viscous at low temperatures and as they weather. Heavy oils and diluted bitumens would have more resistance to flowing or penetrating cracks in ice to reach the water surface than would be the case for light or medium crude oils. During the summer, diluted	Season affects both the behavior of oil in the environment, and the types and abundance of birds that could be exposed to spilled oil. Most aquatic birds migrate south during the winter, unless reliable open water conditions (e.g., fast-moving water where ice does not form) create access to a reliable food supply. Most northern hemisphere birds breed during the summer months, and for some species this implies colonial nesting habits. Birds may also congregate in

Table 7-40 Biological Receptor: Semi-Aquatic Birds

Environmental Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
			bitumens would flow readily and spread rapidly while fresh. Weathering in the first 24 to 48 hours would result in increasing viscosity and density, limiting further spreading of the oil on the water surface.	feeding or staging areas during seasonal migration events.
Weather conditions—rainfall and water levels	Periods of high rainfall and high water levels could transport spilled crude oil into riparian areas, in addition to potentially increasing downstream transport distances. This would affect all crude oil types. If crude oil is transported into riparian areas, then different species of birds (e.g., shorebirds and ground-feeding birds) could be exposed to the oil and its effects either through direct contact with oil, or though food chain effects as PAHs and oily residues are ingested with food and associated soil.			
Weather conditions—temperature	The survival of oiled birds could be affected by ambient temperatures, regardless of season. The primary cause of mortality in oiled birds is hypothermia caused by the loss of insulation value of oiled feathers. Birds that are in contact with cold water experience far greater thermal stress than birds that are in contact with air. Oiled birds may move onto land to reduce thermal stress. Such birds might survive for longer periods of time (providing an opportunity for capture and rehabilitation) during periods of warm weather, as compared to periods of cold weather.			
Slope	Lakes have negligible slope, and therefore the short-term distribution of crude oil on the water surface may be determined primarily by wind. Streams and rivers have slope, which determines the downstream water flow velocity, as well as influencing the turbulence of that flow. Slope therefore helps to determine the downstream transport distance for spilled oil before emergency response can be effectively applied. This can affect the types of habitat that the spilled oil could affect, as well as the numbers and types of birds.			

7.1.3.7 Semi-Aquatic Mammals

7.1.3.7.1 Description

Most North American mammals are terrestrial in nature. However, some species have evolved to use aquatic environments as facultative or obligate habitat (Vaughan et al. 2000). Species inhabiting aquatic environments are more likely to be exposed to and be affected by oil in the event of a release because oil disperses more readily in aquatic environments, and because contact with cold water results in a much higher level of thermal stress on oiled animals than exposure to air (McEwan et al. 1974; Knopper et al. 2016). Semi-aquatic species also tend to seek refuge in their aquatic environment rather than disperse over land. For example, beavers, muskrats and otters will seek refuge in lodges when threatened by predators. Therefore, semi-aquatic mammals were selected as a receptor group to focus upon for this effects assessment. The semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, but this assessment will focus particularly upon species that have a primary association with the aquatic environment such as muskrat, beaver, American mink, river otter, and the water shrew.

Among semi-aquatic mammals, moose are the least dependent on aquatic environments. Their association is based on the preferential foraging for vegetation in lakes and wetlands during the open-water season (Franzmann 1981), which would limit oil exposure to periods when hypothermia would be less severe than during the winter period. Moose are large-bodied, and would be less prone to hypothermia due to oiling of the fur than smaller mammals. The raccoon is less dependent on aquatic environments, but is associated with riparian areas, foraging on aquatic invertebrates and fish during the open-water season (Lotze and Anderson 1979). Both moose and raccoon would be expected to have the behavioral plasticity to select habitat where thermal stress would be reduced if they were to be oiled, and in addition would be able to continue to feed even when denied access to an oiled watercourse. These species are considered to have low (i.e., moose) or moderate (i.e., raccoon) sensitivity to crude oil exposure.

Other semi-aquatic herbivores in this receptor group include beaver and muskrat. These species inhabit aquatic environments year-round and overwinter in lodges located on lakes, rivers, or wetlands (Jenkins and Busher 1979; Willner et al. 1980). Both species eat a mixture of aquatic and terrestrial vegetation. American mink, North American river otter, and northern water shrews are also semi-aquatic species that forage year-round in aquatic environments, raising their young in dens along shorelines or in abandoned beaver lodges. These are primarily carnivorous species that generally eat a mixture of fish and invertebrates (Larivière 1999; Larivière and Walton 1998; Beneski and Stinson 1987). These species would have little or no opportunity to select environments where contact with water could be avoided if they were to become oiled, and similarly little behavioral plasticity to continue feeding if forced away from the aquatic environment. These species are considered to have high sensitivity to crude oil exposure.

Among semi-aquatic mammals, only the moose (Special Concern) is listed under either the federal *Species at Risk Act* or under Minnesota's Endangered Species Statutes (MN DNR 2013; USFWS 2016).

7.1.3.7.2 Observed Effects

A number of hydrocarbon oil releases from pipelines, as well as rail car and storage tank examples, provide an overview of observed effects of oil releases on mammals in aquatic environments (e.g., river, lakes and wetlands) similar to those that could be encountered in Minnesota. This review is not exhaustive, but provides a range of observed effects of a variety of oil types on semi-aquatic mammals, under different environmental conditions. The case studies provide an empirical basis from which the likely effects of oil releases on semi-aquatic mammals can be predicted, with consideration of the modifying effects of oil type, and environmental factors.

> ***Ashland Petroleum**: On January 2, 1988, a 40 year old storage tank collapsed at the Ashland Oil Facility in West Elizabeth, Pennsylvania. The tank collapse released approximately 90,500 barrels of diesel fuel, of which 23,800 barrels flowed into the Monongahela River 27 miles south of Pittsburgh, Pennsylvania. As the release moved downstream, water supplies were contaminated, resulting in the disruption of water services to riverside cities in Pennsylvania, Ohio, and West Virginia. As of January 7, only 1,900 barrels of product had been recovered (NOAA 1992). The effort to recover the oil was hindered by dams and locks along the Ohio River, ice cover, emulsification of the oil, and dispersion of the oil into the water. The Pennsylvania Game Commission assisted by volunteers set up bird cleaning programs and monitored for oiled wildlife, though efforts were hampered by weather conditions and partial ice cover that resulted in rescue workers not accessing areas where wildlife might concentrate. While bird fatalities were reported as a result of the release, there were no semi-aquatic mammals reportedly affected (Miklaucic and Saseen 1989), though there would have likely been muskrat, beaver, mink, and river otter inhabiting the aquatic environment.*

> ***Exxon Bayway**: On January 2, 1990, an underwater pipeline released approximately 13,500 barrels of No. 2 heating oil into the Arthur Kill waterway at the mouth of Morse Creek between New Jersey and Staten Island, New York (NOAA 1992). Initial response efforts focused on containment of the release and removal of the larger masses of oil. Concentrations of floating oil and mousse in the open water, primarily between Howland Hook and Fresh Kills, were collected by self-propelled skimmers. Oil concentrated and stranded above the berm on the beaches from Cedar Point to Rossville as well as in other natural areas. Factors resulting in the dispersal of oil beyond the berm were not reported, though it could have been due to tidal and wave action. Environmentally sensitive areas were protected with boom and skimmers that collected the larger masses of free-floating oil. Through February 20, 1990, monitoring crews reported 29 dead muskrats among other affected wildlife (NOAA 1992).*

***Lakehead**: On March 3, 1991, a Lakehead Pipeline Company, Inc. owned pipeline ruptured and released over 40,000 barrels of crude oil (NOAA 1992) approximately two miles north of Grand Rapids. Some of the oil spread onto the 18 in. thick ice sheets on the Prairie River. Oil formed into 8 inch deep pools on top of the ice in the middle of the river and was also present under the ice. Vacuum trucks were used by clean-up personnel to remove the oil from the surface of the ice. Workers used squeegees to push the oil along the ice to a removal location. Booms were used on the river by cutting a slot through the ice cover with chainsaws. Ice that had been permeated with oil was chopped into blocks small enough to be carried away to a separate part of the river. Clean-up personnel sprayed the ice blocks with hot water to wash out the oil, which was then recovered with skimmers. Blocks that were only slightly contaminated were moved to lined holding tanks and broken up. The crushed ice was then allowed to melt to recover residual oil. There were no reports of semi-aquatic mammals affected by the oil release; effects to fish and wildlife were reported as minimal by the MN DNR (Telegraph Herald 1991), likely due to ice-covered conditions at the time of the release.*

***OSSA II**: On January 30, 2000, an estimated 29,000 barrels of mixed heavy crude oil and diluent (combined density of approximately 0.8 g/mL) were released from the Transredes S.A operated OSSA II pipeline at the Rio Desaguadero river crossing in Bolivia as the river was rising to peak flood conditions (Lee et al. 2001, 2002; Owens and Henshaw 2002). Due to the very high river flow and water velocity conditions, and perhaps also due to the low viscosity of the oil which would allow it to become dispersed into the water as fine droplets, oil was found up to 230 miles downstream from the release location. For the most part, the surface oil was deposited in strips, generally 3 to 6 ft wide and up to 0.5 to 1 inch thick. Many sections of river bank had a horizontal line of oil (a bathtub ring) where the oil was stranded, indicating the water level at the time (Owens and Henshaw 2002). The response effort included more than 3,600 people who recovered the oil within three months. Wasson et al. (2000; in Owens and Henshaw 2002) reported on the wildlife effects of the release and indicated that no wildlife fatalities other than a small number of birds were observed during the extensive post-release monitoring.*

***Pine River**: On August 1, 2000, a Pembina Pipeline Corp. pipeline failure released approximately 6,200 barrels of light crude oil, of which an estimated 2,800 barrels entered the Pine River 70 miles upstream of Chetwynd, British Columbia (BC MOE 2000a). An estimated 300 to 710 barrels remained unaccounted for following the clean-up and remediation (Goldberg 2011). Most of the oil unaccounted for was considered likely to be entrained in sediment or debris in the river channel. Response measures included placing two containment systems, one approximately 14 miles downstream and a second approximately 19 miles downstream (BC MOE 2000c). The river was flowing at a low stage at the time of the release (approximately 5,680 ft^3/s measured at a station 100 miles downstream compared to flow rates above 31,880 ft^3/s during late spring and early summer) (Bustard and Miles 2011). The Pine River has a gradient of approximately 0.225% in the first 25 miles downstream from the release location, decreasing to 0.1% farther*

downstream (Bustard and Miles 2011). There were incidental reports of beaver, otter, and mink being affected, though no injured or oiled mammals were detected or captured during the wildlife monitoring program (BC MOE 2000b).

***Wabamun Lake**: On August 3, 2005, a Canadian National freight train derailed near the Village of Whitewood Sands, Alberta, releasing approximately 4,500 barrels of Bunker C fuel oil (Heavy Fuel Oil 7102; Hollebone et al. 2011) and 550 barrels of pole treating oil. An estimated 950 barrels of the Bunker C oil entered Wabamun Lake where it formed a thick black slick approximately 0.5 inch thick (Wernick et al. 2009). The heavy Bunker C product formed several types of aggregates including tar balls, larger tar "logs", submerged sheets, large lumps, tar balls that sometimes reformed into oil slicks, and a "slurry" composed of finely divided organic matter and small oil droplets (Fingas et al. 2006; Hollebone et al. 2011). The oil exhibited a variety of behaviors including submergence, neutral buoyancy, and resurfacing as a result of contacting and taking up foreign matter (such as mineral particles and organic debris) on its path to the lake (Fingas et al. 2006). No dispersions of oil in water were observed in the lake, and no mousse formation was reported in the three years following the release (Hollebone et al. 2011). Overall, the water in the open water area of the lake was reported to be not contaminated with released hydrocarbons or associated metals (Anderson 2006). This is consistent with the very low concentration of relatively water-soluble components (such as BTEX) in the released oil, and the relatively low water solubility of this heavy oil. Similarly, sediments beneath the open water portions of Wabamun Lake were reported not to have been contaminated with petroleum hydrocarbons and were considered to be of similar quality to concentrations measured in 2002 or shortly before the release (Anderson 2006).*

Clean-up activities included cutting of the vegetation and vacuum removal of submerged tar balls entrained in the reed bed detritus (Wernick et al. 2009). A two-year study was conducted to assess regrowth. The study found that exposure to the oil, which was released late in the growing season, did not cause large-scale changes to these emergent plant communities (Wernick et al. 2009). Physical factors such as clean-up activities and vegetation management appeared to be responsible for reduced regrowth observed at some locations (Wernick et al. 2009; Thormann and Bayley 2008).

Despite an intensive wildlife monitoring program, and a wildlife recovery center set up immediately after the release, there were no reports of semi-aquatic mammals injured by the oil, although there was considerable mortality of waterfowl (TSBC 2007). It is likely that beavers, muskrat, mink, and possibly river otters inhabit this system.

***Glenavon**: On April 15, 2007, a release occurred on the Enbridge Line 3 pipeline approximately 1 mile downstream of the Glenavon pump station near Glenavon, Saskatchewan. The rupture released approximately 6,200 barrels of heavy crude oil and affected approximately five acres of a wetland on farmland (TSBC 2008a; SLR Consulting*

2008a). Within two days of the release, approximately half of the crude oil had been recovered (Canada.com 2007a). The site was monitored for one week for exposure of wildlife to oil, and wetlands within 0.6 miles (1 km) were surveyed for any wildlife that may have been oiled initially and moved from the release site. Wildlife monitoring did not detect mammals affected by the release (SLR Consulting 2008a), though it is likely that this system provided habitat for muskrats and possibly mink. The small number of wildlife (five birds) oiled by the release was attributed to the fact that the release occurred at night, and the rapid mobilization of a response to remove oil and reduce exposure of wildlife.

***Marshall**: On July 25, 2010, Enbridge's Line 6B pipeline experienced a release in a wetland near Marshall, Michigan. Approximately 20,000 barrels of heavy crude oil containing diluted bitumen were released over a period of about 17 hours. The pipeline contained two different batches of crude oil at the time of the release (NTSB 2012 a). It is estimated that the released oil consisted of approximately 77% CLWB diluted bitumen and 23% Western Canadian Select, also diluted bitumen (Enbridge 2013a). Of this, approximately 8,000 barrels reached Talmadge Creek and the Kalamazoo River (Enbridge 2013a). Wildlife monitoring programs reported that 40 mammals were either found dead or subsequently died during rehabilitation (USFWS et al. 2015a). In addition, 23 oiled mammals were captured, successfully rehabilitated, and released. An unknown number of mammals are assumed to have been oiled but never found or captured. The primary species reported affected were muskrat (45%), raccoon (13%), and beaver (13%) (USFWS et al. 2015a).*

***Rainbow**: On April 28, 2011, a pipeline owned by Plains Midstream Canada released approximately 28,000 barrels of sweet crude oil into a muskeg/stagnant water area near the community of Little Buffalo in the Peace River region of Alberta. The release occurred on a hillside, and the oil flowed a half mile down the pipeline ROW and pooled in a low-lying area containing abandoned beaver ponds. The release encompassed an area of approximately 20 acres (ERCB 2013). As part of the response, wildlife mitigation measures, which included fencing and various deterrents, were implemented (ERCB 2013). Despite spill-response wildlife-mitigation measures, wildlife mortality included 11 beavers and several small rodents (ERCB 2013) during response activities up through November 2012. No cause-of-mortality analysis was conducted for the deceased wildlife, but it is presumed that oiling was the likely cause.*

***2011 Yellowstone River**: On July 1, 2011, flood conditions in the Yellowstone River resulted in a release from the ExxonMobil Silvertip Pipeline carrying medium sour crude oil near Laurel, Montana. Riverbed erosion exposed the 12-inch pipeline beneath the crossing, and debris caught on the washed-out pipeline causing stress, resulting in a clean break. The failure was detected at the pipeline control center and the line was shut down within 10 minutes (USDOT 2012). Approximately 1,500 barrels of crude oil was released into the Yellowstone River (USDOT 2012). The affected reach of the Yellowstone River has an*

average gradient of 0.17%. Crude oil affected primarily shorelines and banks immediately downstream of the release site (MT DEQ 2015b). According to the USEPA (2011), no oiling of semi-aquatic mammals was reported, though muskrats, mink, river otters, and possibly beavers likely inhabited the area.

***Red Deer River**: On June 7, 2012 a Plains Midstream Canada ULC (Plains) pipeline released approximately 2,900 barrels of light crude oil into the Red Deer River downstream of Sundre, Alberta as a result of high water levels in the river that exposed the pipeline and caused structural damage (AER 2014). The migration of surface oil was stopped by booms placed at Gleniffer Lake, but dissolved hydrocarbons continued to move downstream. This resulted in potential for both toxicological and physical effects upstream of the booms, but limited potential for physical effects downstream (Teichreb 2014). Two beavers were reported among the affected wildlife (Derworiz 2012). Officials with Alberta Environment indicated that effects to wildlife were minimal (Derworiz 2012).*

***Line 37**: On June 22, 2013, unusually heavy rains caused ground movement that compromised the integrity of the Enbridge Line 37 pipeline approximately 1 mile north of the terminal in Cheecham, Alberta. The resulting failure released approximately 1,300 barrels of synthetic light crude oil underground with some oil seeping to the surface where it flowed overland entering a wetland and unnamed lake (Enbridge 2013c). Initial clean-up and remediation recovered 93% of the crude oil with the remaining oil found in soils and the fen. No affected semi-aquatic mammals were detected (Focus Wildlife Canada 2013), though it is likely that muskrat and mink inhabited the wetland.*

***Mid Valley**: On October 13, 2014, a Sunoco pipeline release occurred near Mooringsport, Louisiana, resulting in approximately 4,500 barrels of sweet crude oil entering the Miller branch of the Tete Bayou, which feeds into Caddo Lake. Although containment booms prevented the oil from entering Caddo Lake, approximately 10 miles of the creek were affected. Media reported that 486 dead animals were collected and 47 were cleaned and released (Welborn 2014a). Most of the animals were crawfish and amphibians, but numbers and species were not provided. No semi-aquatic mammals were reportedly affected (Welborn 2014b), though this area would likely be inhabited by nutria, muskrat, river otter, beaver, and mink.*

***Yellowstone River**: On January 17, 2015, a Bridger Pipeline LLC pipeline released approximately 715 barrels of Bakken crude oil (estimates ranged from 300 to 1,200 barrels) into the Yellowstone River approximately 5 miles upstream of Glendive, Montana (MT DEQ 2015b). The pipeline breach occurred where the pipeline crossed under the river. Winter conditions resulted in extensive ice cover, but aerial patrols discovered oil as far as 25 miles downstream of Glendive (The Guardian 2015). Booms were deployed on the ice and in areas of open water downstream to collect oil from the surface (Hirji 2015) but winter conditions combined with thawing resulted in unsafe working conditions and only a limited amount of oil (approximately 60 barrels, MT DEQ 2015a) was recovered*

from the river. There were no reports of oiled wildlife (including mammals) or dead fish (Stuart 2015). The Montana Departments of Natural Resources and Conservation and Fish, Wildlife and Parks expressed concern that the most significant source of damage to the riverine system was the physical damage caused by response crews and equipment during clean-up operations (MT DEQ 2015a.

7.1.3.7.3 Expected Effects of Released Oils

The case studies presented in the foregoing section highlight some of the key factors of oil releases in aquatic environments on semi-aquatic mammals.

As previously indicated, semi-aquatic mammals are expected to be more vulnerable than terrestrial mammals since they rely on aquatic system for all or a portion of their life cycle, and releases into aquatic environments may result in oil dispersing or being transported further from the release site. Unlike waterbirds that often flock and congregate in large numbers (e.g., ducks, geese, gulls) which can be susceptible to a release, semi-aquatic mammals are typically territorial species that are more evenly distributed and have lower densities spread across suitable habitat in the landscape. Consequently for semi-aquatic mammals, the potential effects of an oil spill on regional populations are expected to be relatively low. However, there are also exceptions to low density mammal populations. Muskrats are occasionally found in high densities in wetland systems, making local populations more vulnerable to releases.

The effects of hydrocarbon releases on semi-aquatic mammals can be difficult to quantify directly because of challenges associated with detecting dead and injured individuals post-release. Bowyer et al. (2003) indicated that searching shorelines was not a reliable method of locating dead river otters following a release. This is likely a function of many semi-aquatic mammals (i.e., beavers, mink, muskrat, and otter) seeking refuge in lodges or burrows out of sight when distressed, which prevents detection. Greer et al. (2005) reported that 70 muskrats were recovered during monitoring programs following a crude oil release, but their assessment indicated that this represented less than 20% of the likely affected muskrats based on population estimates within the affected area. However, this is not likely to be the case for a large mammal such as the moose, which is more easily observed than aquatic mammals. The case studies do not provide any records of oiled or dead moose (or other ungulates) following an oil release, and it is concluded that these animals are not highly exposed to crude oil release, or highly sensitive to oiling in the event of such exposure.

Effects to semi-aquatic mammals, like other species of wildlife, are typically described in terms of three types of effects: direct physical effects, direct toxicological effects, and indirect effects through changes to habitat (e.g., land cover and food availability) (Albers 2003; Malcolm and Shore 2003; Lee et al. 2015). These three types of effects on semi-aquatic mammals are discussed below.

7.1.3.7.3.1 Direct Physical Effects on Semi-aquatic Mammals

The most frequently reported direct physical effect of a hydrocarbon release is the adhesion of oil to the fur of semi-aquatic mammals and the subsequent loss of insulation and buoyancy. This is generally considered the most adverse of effects to this receptor group (Albers 2003). Mammals rely on fur for thermal regulation, and aquatic mammals have fur that is adapted to repel water and maintain insulation under water. Loss of water repellency as a result of contact with oil and associated hypothermia can greatly reduce the survival of semi-aquatic mammals and rapidly result in death (McEwan et al. 1974; Kooyman et al. 1977; Wolfe and Esher 1981; Lipscomb et al. 1994).

Several factors affect the severity of the effects of oiling of fur. Lower ambient temperature will amplify the physiological effects of reduced insulation, because of the increased heat loss with increased temperature gradients between organisms and the ambient temperature (i.e., colder air or water temperatures). Smaller organisms (e.g., shrews) are likely to succumb to physical oiling at a faster rate than larger organisms (e.g., moose) because the surface area to volume ratio of smaller organisms is larger resulting in a greater rate of heat loss per volume, reducing body temperatures faster in smaller organisms. Exposure of an oiled animal to water also results in much greater thermal stress than exposure of the same animal to ambient air (McEwan et al. 1974; Knopper et al. 2016).

At higher temperatures, in addition to a reduced heat gradient, oil tends to weather at a faster rate, shortening the duration of insulation loss reducing the potential for adverse effects (Hurst and Oritsland 1982). However, the severity of effect also depends on the type of crude oil released. Hurst and Oritsland (1982) studied the effect of oiling on the insulation of polar bear fur using different oil types and found that thermal conductivity increased with increasing viscosity of the oils, likely due to prolonged matting of the fur by heavier oils. Weathered diluted bitumens have both high density and viscosity, and are more adhesive than other crude oils (NAS 2016). This would reduce the likelihood of unassisted wildlife survival and recovery from oiling for diluted bitumens, relative to that for lighter crude oils.

7.1.3.7.3.2 Direct Toxicological Effects on Semi-aquatic Mammals

Acute toxicity of hydrocarbons is generally the result of narcosis from exposure to certain components of oil, namely some alkanes, mono-aromatics (BTEX) and PAHs (2-ringed naphthalenes) (Dupuis and Ucan-Marin 2015). Exposure to sufficient quantities of these low molecular weight hydrocarbons typically results in acute narcotic effects shortly after an oil release. This effect is more pronounced at the site of release prior to vapors being diluted in the environment or evaporating from the water surface into the atmosphere. In semi-aquatic mammals, the more important exposure routes are direct ingestion of oil or contaminated food, and inhalation. While dermal absorption may occur, exposure is reduced by the fur of semi-aquatic furbearers, particularly for heavier oil types that would have lower potential to penetrate the fur and contact the animal's skin. Semi-aquatic mammals may ingest oil following physical oiling of their fur by grooming and cleaning themselves to remove the contaminants (McEwan et al. 1974).

The contamination of water surfaces by oil may increase the inhalation exposure to toxic components for semi-aquatic mammals that are swimming on the surface (Peterson 2001; Frost et al. 1994). Inhalation of vapors was suggested as a probable cause of interstitial pulmonary emphysema following necropsies of dead sea-otters, after the Exxon Valdez spill (Lipscomb et al. 1994). This could be of similar concern for species such as beaver, river otter, and muskrats which also spend the majority of their life cycle in water. However, the ultimate cause of death of recovered wildlife following a release is challenging as few animals are necropsied and results reported. Baker et al. (1981) reported on the death of otters near the Sullom Voe oil terminal, in the Shetland Islands, United Kingdom, following a release of Bunker C fuel oil on December 31, 1978. Heavy fuel oil (bunker C) would contain much less volatile material than most crude oils, so narcosis as a result of inhalation is unlikely to cause death; however, the heavy fuel oil would also contain much higher levels of PAHs than most crude oils (Dupuis and Ucan-Marin 2015). At least 13 otters died following the Sullom Voe release, although others presumably also died but were not detected (Baker at al. 1981). Five animals, with external oiling ranging from minor on the rump and tail, to heavy coating the entire body, were sent for post-mortem examination. The cause of death for each of the animals examined was determined to be a hemorrhagic gastro-enteropathy, presumably caused by ingestion of oil as a result of grooming. However, hypothermia was also considered to be a potential contributor to the death of these animals (Baker et al. 1981). Two dead sheep, which had been eating oil contaminated seaweed, were also examined and showed oesophageal and gastric ulceration (Baker et al. 1981).

Sublethal effects of oil exposure in mammals also occur. Schwartz et al. (2004a, 2004b) determined that exposure of mink to bunker C fuel oil, at low concentrations (500 ppm in diet) for extended periods of time, would result in immune system, systemic, and hematological responses with potential consequences for survival and reproduction in individuals. These effects may not be observed in field monitoring programs or during wildlife rehabilitation programs following a release. Similar results were also observed in studies by Mohr et al. (2008, 2010). Note, however, that bunker C oil contains different proportions of toxic hydrocarbons (e.g., less BTEX, but more PAHs; Dupuis and Ucan-Marin 2015) than diluted bitumens and conventional crude oils.

7.1.3.7.3.3 Indirect Effects of Oil Release on Semi-aquatic Mammals

Oil releases may have indirect effects on semi-aquatic mammals through effects to habitat or changes in food quality or availability. Habitat loss is more easily quantified than effects to individuals, because suitable habitat characteristics of mammals are generally well known, and effects are more easily quantified.

Indirect effects on individuals may also occur as a result of rehabilitating efforts alone. Ben-David et al. (2002) examined the survival rate of captured and rehabilitated otters exposed to oiling compared to wild otters. They found that survival was lower for captured and released otters, but the effect of oiling was not a factor because the survival rates of captured, oiled, and rehabilitated otters were similar to those captured and released without oiling (i.e., capture controls), indicating that the toxicological effect of oiling was not significant. Otters are known to

suffer from capture myopathy (Hartup et al. 1999), which would have implications for indirect effects of rehabilitation following oiling of this species, and potentially other wildlife species.

Bowyer et al. (2003) noted that following the Exxon Valdez spill, river otters had larger home ranges, lower body mass, and a less varied diet than individuals in control sites. Density of otters did not differ between sites, suggesting no population level effects occurred. However, it does suggest that otters may require larger areas to obtain sufficient food sources in areas affected by oil. Loss or degradation of habitat may lead to dispersal of individuals in search of suitable habitat, which can reduce survival through competition between immigrants and local residents, particularly in territorial species (Crawford et al. 2015).

Wolfe and Esher (1981) found that rice rat swimming behavior was affected when oil was added to swim tanks (both south Texan and empire crudes) compared to controls, and individuals avoided swimming in oiled water. The higher adhesion rate of weathered diluted bitumens and heavy crudes (NAS 2016) also requires more intensive remediation efforts that could result in more severe changes to habitat quality, though effects are typically of short to medium duration (e.g., one to two years) as was observed from the Glenavon, Rainbow, and Wabamun releases described above.

Table 7-41 and Table 7-42 provide a summary of the expected environmental effects of oil releases to semi-aquatic mammals in inland environments. Table 7-41 considers the effects of specific oil characteristics on the expected types and scope of environmental effects. Table 7-42 considers the effects of environmental factors characteristics on the expected types and scope of effects.

Table 7-41 Biological Receptor: Semi-Aquatic Mammals

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—buoyancy	Light crude oils typically have a relatively low density (0.78-0.88 g/mL, Dupuis and Ucan-Marin 2015) and are buoyant in freshwater aquatic environments.	Medium crude oils typically have an intermediate density compared to light and heavy crudes, and are buoyant in freshwater aquatic environments (Dupuis and Ucan-Marin 2015).	Heavy conventional crude oils can have density ranging of 0.88 to 1.00 g/mL, while fresh diluted bitumen will have density less than 0.94 g/mL (Dupuis and Ucan-Marin 2015).	While raw bitumen has a higher density than water, diluted bitumen is less dense and limited evaporative mass loss at environmentally-relevant temperatures suggests that weathered dilbit will remain afloat as it will retain sufficient diluent to maintain a lower density ((Lee et al. 2015; see also Section 7.1.2). Recovery of released oil is facilitated if the oil floats on the surface of the water. A more rapid recovery of oil will reduce the potential exposure duration to semi-aquatic mammals. Buoyancy of oil will also prevent contact with semi-aquatic mammals swimming submerged or foraging in the benthic environment.
Oil properties—viscosity	Light crudes will spread rapidly on water because of their low viscosity (1 to 5 mPa•s, NAS 2016).	Medium crudes have an intermediate viscosity (8 to 112 mPa•s, NAS 2016).	Heavy crudes (820 to 475,000 mPa•s) and diluted bitumens (270 to 50,000 mPa•s) weather to high viscosity (NAS 2016).	Viscosity is a function of oil chemistry. Diluted bitumens tend to display a more rapid increase in viscosity due to weathering of low molecular weight hydrocarbons associated primarily with the diluent than conventional heavy crude oils. Oil having low viscosity will rapidly spread across the water surface forming a thin and relatively uniform slick. More viscous oils will spread more slowly and may exhibit thicker but patchier slicks with associated sheens. Higher viscosity oils will have lower dispersion and generally result in smaller spatial areas where semi-aquatic mammals may come in contact with the oil. Oil viscosity also influences adhesion, which is relevant to physical oiling (see Oil Properties – adhesion below)

Table 7-41 Biological Receptor: Semi-Aquatic Mammals

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—adhesion	Light crudes have low adhesion and viscosity (NAS 2016) and can be expected to penetrate the fur to contact skin.	Medium crudes have an intermediate adhesion and viscosity (NAS 2016). Medium crude oils also readily penetrate fur to contact skin.	Heavy crudes and particularly diluted bitumens are highly adhesive and more viscous than light and medium crude oils. Fresh diluted bitumens have relatively low viscosity, and would penetrate fur. However, weathered heavy crudes may tend to stick to the surface of fur without penetrating to contact the skin.	Properties of adhesion and viscosity may change the way that crude oil interacts with fur. Light oils may more readily penetrate fur and reduce insulation; heavy oils, particularly when weathered, may tend to adhere in a thick layer to the hair without immediately penetrating to the skin surface. This results in more difficult cleaning and removal of oils from fur and extended duration of physical effects, though less potential for dermal exposure to toxic hydrocarbon components there is increased potential for ingestion (see toxicity of chemical components discussion below).
Oil properties—toxicity of chemical constituents	Light crude oils often contain high levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, depending on the oil type, but can be high (>10,000 mg/kg) in Bakken oils.	Medium crude oils often contain moderate levels of BTEX and other relatively water soluble hydrocarbons. Levels of TPAH are variable, but can exceed 10,000 mg/kg.	Levels of BTEX and other relatively water soluble constituents are variable: generally low in heavy conventional oils, but variable in diluted bitumens depending upon the nature of the diluent. Levels of TPAH are variable, but typically depleted in napthalenes and less than 10,000 mg/kg.	Acute effects on mammals are generally caused by physical oiling, not related to the BTEX content of the oil. Chronic effects on mammals of released crude oil, if any, are likely due to dietary TPAH exposure. Diluted bitumens do not contain higher concentrations of either BTEX or TPAH than many conventional crude oils (Lee et al. 2015). Diluted bitumens contain the same suite of PAHs as conventional crude oils, but at different relative concentrations due to the highly weathered nature of the bitumen component, and the modifying effect of the diluent. Additional details on the characteristics of diluted bitumen are provided in Section 7.1.2.

Table 7-41 Biological Receptor: Semi-Aquatic Mammals

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil properties—persistence	Light crude oils typically contain only small proportions of higher molecular weight components, such as resins and asphaltenes. Light crude oils generally biodegrade readily.	Medium crude oils contain variable proportions of resins and asphaltenes. Asphaltenes would be removed from synthetic medium crudes during processing of bitumen.	Heavy conventional crude oils and diluted bitumens typically contain higher proportions of resins and asphaltenes, which tend to resist biodegradation.	In general, heavy conventional crude oils and diluted bitumens would be expected to biodegrade less rapidly than light or medium crude oils. However, any oil can be persistent if deposited in an environment where there is little or no available oxygen. Persistence in the environment will directly influence the potential exposure duration of semi-aquatic mammals to oil.

Table 7-42 Biological Receptor: Semi-aquatic Mammals

Environmental Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Habitat type	Light crude oil will spread rapidly due to its low viscosity, potentially resulting in effects over a larger area in lakes and wide rivers.	Medium crude oil has low viscosity, although viscosity increases at lower temperatures, and will behave similarly to light crude oils.	Heavy crude oils have high viscosity. Diluted bitumens also have high viscosity (although reduced while fresh due to the effect of the diluent), potentially resulting in effects over a smaller area in lakes and wide rivers, due to the oil's resistance to spreading in these habitats.	Low viscosity oils will spread more rapidly, and to thinner slicks, than high-viscosity oils. As a result, low viscosity oils have a higher potential to affect a larger area of habitat, particularly open-water habitats such as lakes and wide rivers, than higher viscosity oils. At the same time, higher viscosity oils will tend to form thicker slicks than low viscosity oils. This could lead to a contrast of "more mammals oiled less heavily" with lighter oils, as compared to fewer mammals oiled more heavily with heavier oils.
Season	Light oils remain fluid at low temperature and retain the potential to spread rapidly during the winter. Light oils may penetrate cracks in ice or close to shore, allowing the oil to get beneath the ice and spread downstream. In summer, light crude oils would also flow readily and spread rapidly, having the potential to contact larger numbers of mammals than heavier, more viscous oils.	Medium oils are slightly more viscous than light oils, and would also tend to flow readily under winter conditions. Medium crude oils would tend to flow readily and spread rapidly under summer conditions.	Heavy oils become much more viscous at low temperatures, and as they weather. Heavy oils and diluted bitumens would have more resistance to flowing or penetrating cracks in ice to reach the water surface than would be the case for light or medium crude oils. During the summer, diluted bitumens would flow readily and spread rapidly while fresh. Weathering in the first 24 to 48 hours would result in increasing viscosity and density, limiting further spreading of the oil on the water surface.	Season affects both the behavior of oil in the environment, and the distribution and behavior of mammals that could be exposed to released oil. Some mammals do not use aquatic environments during the winter (e.g., moose and raccoon), while others become isolated within an aquatic system (e.g., beaver and muskrat) and would be more vulnerable to a release into an aquatic system. During the open water season, mammals have the ability to disperse from waterbodies and seek new habitat.
Weather	Periods of high rainfall and high water levels could transport released crude oil into riparian areas, in addition to potentially increasing			

Environmental Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
conditions—rainfall and water levels	downstream transport distances. This would affect all crude oil types. If crude oil is transported into riparian areas, then mammals that use terrestrial areas more (e.g., raccoons, moose) could be exposed to the oil and its effects either through direct contact with oil, or though food chain effects as PAHs and oily residues are ingested with food and associated soil.			
Weather conditions—temperature	The survival of oiled mammals could be affected by ambient temperatures, regardless of season. Mammals that are in contact with cold water experience far greater thermal stress than mammals that are in contact with air; especially for more aquatic mammal species (e.g., muskrat, beaver, otter). Some oiled mammals may avoid entering the water to reduce thermal stress. Those individuals might survive for longer periods of time during periods of warm weather as compared to periods of cold weather, providing greater opportunity for capture and rehabilitation.			
Slope	Lakes have negligible slope, and therefore the short-term distribution of crude oil on the water surface may be determined primarily by wind. Streams and rivers have slope, which determines the downstream water flow velocity, as well as influencing the turbulence of that flow. Slope therefore helps to determine the downstream transport distance for spilled oil before emergency response can be effectively applied. This can affect the types of habitat that the spilled oil could affect, as well as the numbers and types of birds.			

7.1.4 Human Receptors

7.1.4.1 Human Health

7.1.4.1.1 Description

Human health relates to the physical health and well-being of people living or using lands near the Project, and is intrinsically important to the public. Many factors may influence a community's sense of well-being, including concepts such as trust and risk perception. However, in the context of an oil release, public health concerns are focused on the potential environmental effects to health that could arise from exposure to contaminants. People want to understand how their health may be affected by oil-related contaminants in the air they breathe, the water they drink, and the food they eat.

The typical health effects associated with short-term (acute) inhalation of volatiles from crude oil (including petroleum hydrocarbons and hydrogen sulfide) are headaches, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term skin contact with oil may result in dermatitis (Solomon and Janssen 2010). The literature suggests that these acute health effects observed in residents and clean-up workers do not persist over the long-term (Eykelbosh 2014). However, relatively little has been published regarding the long-term effects of exposure to an oil release. The International Agency for Research on Cancer (IARC 1989) has determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans.

Crude oils are complex mixtures of thousands of PHC, and many non-petroleum compounds. To understand how crude oil may affect human health, it is necessary to assess the crude oil in terms of the various constituents, or chemicals of potential concern (COPC) that characterize its potential fate, transport, and toxicity in the environment. The primary groupings considered relevant to the assessment of human health are low molecular weight aromatics (BTEX), aliphatic and aromatic PHC fractions, PAHs, and other volatiles (including other types of organic compounds containing sulfur and nitrogen).

Higher molecular weight aliphatic and aromatic hydrocarbons (greater than C_{16}), including higher molecular weight PAHs, exhibit very low to negligible vapor pressure and are typically considered non-volatile. These non-volatile compounds are not expected in to be present in ambient air at substantive concentrations following an oil release, but they may persist in soil or sediment, affecting the biological tissue concentrations of food sources (e.g., fish). Conversely, other COPC such as BTEX and lower molecular weight hydrocarbons are highly volatile and may be relatively water soluble. While these lower molecular weight compounds are expected to be present in air and water in the short term, they are unlikely to persist as residues in sediment or biological tissues in the longer term.

7.1.4.1.2 Observed Effects

The following section summarizes a review of some historical oil releases and reported health effects. For some spills, no health effects were reported, but regulatory agencies imposed restrictions (e.g., evacuations, closure of potable water intakes, fishery closures) as a precaution to prevent exposures above levels that could be associated with health effects. These instances of regulatory restrictions are also considered relevant to the assessment of human health.

***Pine River, British Columbia**: On August 1, 2000, a failure of the Pembina Petroleum pipeline resulted in the release of approximately 6,200 barrels (985 m^3) of light crude oil. Approximately half of the released oil was estimated to have reached the Pine River (Goldberg 2011), which was experiencing low flows at the time of the release (5,700 ft^3/s at time of release versus 32,000 ft^3/s in late spring/early summer) (Bustard and Miles 2011). Of the oil that reached the Pine River, approximately 2,830 barrels (450 m^3) was later recovered (BC MOE 2000a). Following the release, the Pine River was closed to angling and area residents were advised not to use water directly from the river (BC MOE 2000b). The water intake for the water treatment plant in the Town of Chetwynd, located 68 miles (110 km) downstream of release was temporarily closed, and the use of many groundwater wells near the river was discontinued (BC MOE 2000a). The District of Chetwynd was able to resume use of the Pine River for their water supply three years later (Brown 2003).*

***Cass Lake, Minnesota**: In May 2001, during the installation of shallow groundwater monitoring wells at the Enbridge Energy Limited Partnerships South Cass Lake Pump Station in Cass Lake, Minnesota, crude oil contamination was detected in the subsurface. The site is located within the reservation environment of the Leech Lake Band of Ojibwe, and 12 residential homes and businesses, were identified within 0.6 miles of the of the site. There were concerns that the crude oil would affect domestic water-supply wells and result in human health risks. Initial groundwater samples collected in 2001 showed a maximum benzene concentration of 6,500 µg/L close to the source (Wenck Associates 2006), and a maximum benzene concentration 1,300 µg/L offsite. A contaminant plume of greater than 10 µg/L of benzene extends approximately 500 ft down-gradient from the crude oil source, 130 ft across, and vertically 6 to 10 ft (Drennan et al. 2010). Since drinking water wells were not located within 0.5 miles down-gradient of site, they were not affected by the crude oil (Natural Resources Engineering Company 2004).*

***Burnaby, British Columbia**: In July 2007, a backhoe ruptured the Trans Mountain pipeline in Burnaby, British Columbia. Heavy crude oil (diluted bitumen) sprayed 40 to 50 ft into the air for approximately 25 minutes, covering the surrounding area (TSBC 2008b). Several people were reportedly covered with oil, including emergency workers, two firefighters, and two members of the public (TSBC 2008b). Subsequent assessment classified 8 residential properties as heavily oiled, 15 as moderately oiled, and 21 as lightly oiled (TSBC 2008b). Approximately 250 people voluntarily left their homes (TSBS 2008b, Trans*

Mountain 2015). More than half of the people returned later that night and another 100 people returned the following day (Trans Mountain 2015). Residents from the most heavily oiled properties were housed in longer-term accommodations (Trans Mountain 2015). Air quality monitoring was initiated immediately after the release. Very high volatile organic compound levels were detected during the early stages of the incident, but declined rapidly as clean-up progressed (Eykelbosh 2014). Affected residents reported a number of health effects, including headaches (15%), respiratory tract irritation (8%), nausea (6%), dizziness (3%), and eye irritation (3%) (Eykelbosh 2014).

***Salt Lake City, Utah**: On June 12, 2010, approximately 800 barrels of medium crude oil were released from a Chevron crude oil transfer pipeline, spilling into Red Butte Creek in Salt Lake City, Utah. The creek flows through residential and commercial properties, affecting an estimated 600 homes and 1,800 residents (Utah Department of Health 2011).*

Environmental monitoring included both water and air sampling. Air monitoring for specific compounds (benzene, toluene, ethylbenzene, xylenes) was initiated on June 13, 2010. The highest benzene concentration in indoor air at a residential property was 1.9 µg/m^3 (0.60 ppb), while outdoor air sampling indicated a maximum benzene concentration of 1.7 µg/m^3 (0.53 ppb) (Utah Department of Health 2011). The maximum benzene concentration in water samples from Red Butte Creek was 27.6 µg/L (Utah Department of Health 2011).

A public health assessment was completed to address community health concerns related to the crude oil contaminants, specifically focusing on water and air. The public health assessment concluded that measured concentrations of crude oil components in water did not represent a health hazard to the community from ingestion or dermal absorption and that measured concentrations of volatile components in air did not have the potential to harm human health through inhalation (Utah Department of Health 2011). However, because air sampling did not begin until one day after the release, the health risk from inhalation of vapors during the minutes and hours following the release could not be determined.

In November 2010, a survey was sent to over 600 residences in the community and over 131 responses were received (Utah Department of Health 2011). Of those that responded, 23% indicated the creek ran through their backyard, and 73% said they had smelled an unusual odor in the early days of the release (Utah Department of Health 2011). Respondents answered questions about the symptoms they had experienced at the onset of the release and at the time of the survey. From the data, the most common reported symptoms were nausea, headache, irritated eyes, and anxiety (Utah Department of Health 2011). The number of people experiencing symptoms decreased from June 2010 when the release occurred through November 2010 when the public health assessment survey was distributed (Utah Department of Health 2011). There was no control group identified for the study.

***Marshall, Michigan**: On July 25, 2010, approximately 20,000 barrels of heavy crude oil containing diluted bitumen were released over a period of approximately 17 hours from Enbridge's Line 6B pipeline near Marshall, Michigan (NTSB 2012a). At the time of the release, the pipeline contained two different batches of crude oil estimated to consist of approximately 77% CLWB diluted bitumen and 23% Western Canadian Select, also a diluted bitumen (Enbridge 2013a). Of this, approximately 8,000 barrels reached Talmadge Creek and the Kalamazoo River (Enbridge 2013a). These two watercourses were between 25-year and 50-year flood levels at the time of the release (MI DCH 2014b). The oil was transported approximately 37 miles downstream of the release (MI DCH 2013). Approximately 41,500 people were estimated to live within 1 mile of the affected area (MI DHC 2015).*

Air monitoring and sampling activities were initiated in the area of the release on July 26, 2010, and quickly expanded to include other nearby populated areas. Approximately 24 hours after the pipeline burst, benzene concentrations of 9,600 µg/m^3 (3 ppm) were recorded close to the initial release location, at the confluence of the Talmadge and Kalamazoo Rivers (MI DCH 2015). Residents in this area had already relocated due to the odors from the released oil (MDCH 2015). The highest concentrations of benzene reported were approximately 31,900 µg/m^3 (10 ppm), observed approximately two days after the release at a location where no one was living (MI DCH 2015). Lower levels of benzene were measured at the same location or nearby on the same day, and in the days after, indicating that these air concentrations were not sustained (MI DCH 2015).

At the time of the release, the MI DCH (2014b) issued a precautionary advisory against swimming and fishing, and local health departments banned recreational use of the affected river reaches. Surface water samples (collected during July 2010–April 2012) and fish tissue samples (collected in 2010 and 2011) were submitted for analysis of crude oil constituents, particularly PAHs and certain metals, as well as other contaminants not related to crude oil (e.g., mercury and PCBs) to evaluate if the oil release, or the resulting clean-up activities, caused changes to contaminant levels in the fish (MI DCH 2014b). Oil-related and non-oil-related chemicals were measured in the surface water. Only a few chemicals (mostly PAHs) were detected above health-protective screening levels, and these exceedances occurred in only a small percentage of the surface water samples. Nickel and vanadium were not detected in fish filets, but some PAHs were detected in some filets (MI DCH 2014b). Mercury and PCB levels in fish filets were similar to those observed prior to the release (MI DCH 2014b). In June 2012, most of the river was re-opened for recreational use, and the fish consumption advisory in relation to the release was lifted.

Although there was no evidence to suggest that the oil release had contaminated groundwater resources, a precautionary bottled water advisory was issued on July 29, 2010 to allow time for well water samples to be collected and analyzed (MI DCH 2013). Approximately 168 private wells were selected for sampling based on proximity to the

release (i.e., within 200 feet of the high-water level mark from the July 2010 flood event) (MI DCH 2013). Water samples from the wells were analyzed for both crude-oil related chemicals and other chemicals. No oil-related organics above their screening levels were detected in the potable water samples (MI DCH 2013).

Sediment samples collected from the Kalamazoo River and Morrow Lake in the spring of 2011 from areas exhibiting moderate to heavy amounts of submerged oil had detectable concentrations of VOCs, PAHs, TPHs, and metals (i.e., molybdenum, nickel, and vanadium) (MI DCH 2012).

In response to concerns about acute health effects associated with the release, MI DCH collected data from health care providers and the state surveillance system, conducted a door-to-door health survey, and reviewed Poison Control Center hotline reports. Headache, nausea, and respiratory symptoms were the predominant symptoms reported by exposed individuals (MI DCH 2010).

Subsequently, a number of public health assessments were completed in relation to the release. The first addressed concerns related to submerged oil located in the sediment. The study concluded that contact with sediment containing submerged oil, tar patties, or oil sheens could cause temporary health effects such as skin irritation, which would not persist in the absence of continued exposure (MI DCH 2012). The study further concluded that repeated skin contact and accidentally eating a small amount of sediments containing submerged oil would not result in long-lasting health effects or in a higher than normal risk of cancer (MI DCH 2012).

A separate public health assessment was completed to assess potential health effects associated with drinking water from wells located along stretches of Talmadge Creek and the Kalamazoo River. Two oil-related inorganic chemicals (nickel and iron) were found in private drinking water wells, but were at concentrations that would not be expected to produce health effects. The nickel and iron were likely naturally occurring metals (MI DCH 2013). No oil-related organic chemicals were found in the samples of potable well water. Arsenic and lead, two metals not present in crude oil, were present at levels that may harm people's health (MI DCH 2013). MI DCH (2013) concluded that arsenic is a naturally occurring metal in the area and lead could be naturally occurring or be present in people's plumbing.

A third public health assessment addressed health concerns related to exposures to chemicals in surface water and fish. In its assessment, MI DCH (2014b) concluded that chemical levels found in surface water are not expected to cause long-term harm to people's health but, similar to conclusions reached for sediment, people may have temporary health effects, such as skin irritation, from contact with the oil sheen or tar globules in the water. Further, the MI DCH (2014b) concluded that oil-related chemical levels found in fish from the Kalamazoo River and Morrow Lake will not harm people's

health. However, MI DCH (2014b) did issue fish consumption guidelines because of levels of two chemicals not related to the oil release (mercury and PCBs) found in the filets.

The most recent public health assessment addressed concerns related to inhalation of volatile chemicals (MI DCH 2015). The study reviewed the air monitoring and sampling efforts completed during July 2010 through 2012. The study concluded that people experienced short-term effects associated with inhaling oil-related volatiles (headaches, nausea, respiratory discomfort and eye irritation), but that these health effects diminished or stopped once people were no longer breathing the oil-related chemicals (MI DCH 2015). Some people may have experienced anxiety, regardless of exposure (MI DCH 2015). The study further concluded the people did not breathe oil-related chemicals long enough, or at high enough levels, to cause long-term health effects (MI DCH 2015).

***Laurel, Montana**: On July 1, 2011, a break of the ExxonMobil pipeline near Laurel, Montana released an estimated 1,500 barrels of medium crude oil into the Yellowstone River, which was at the peak of a 30-year flood event at the time of the release (MT DEQ 2015c). High flows transported the oil up to 72 miles downstream, although the majority of the effects were observed within 20 miles of the release location (USEPA 2011).*

A number of public drinking water systems obtain water from the Yellowstone River, downstream of the release location. Operators of these systems were notified of the release. Monitoring and testing of the water supply systems for more than 100 contaminants did not identify any exceedances of drinking water standards. In May 2013, the MT DEQ determined that no additional sampling of the downstream public drinking water systems was necessary after tests showed contamination was below human health screening levels (MT DEQ 2013).

Several monitoring wells were installed in areas where crude oil was considered most likely to affect groundwater. Samples were obtained from these wells, as well as from over 300 private wells (MT DEQ 2015b). Crude oil-related petroleum hydrocarbons were not detected in the samples (MT DEQ 2015b). In September 2013, MT DEQ determined that petroleum hydrocarbons from the discharge were not present in groundwater and did not pose an unacceptable risk to public health (MT DEQ 2015b).

A fish consumption advisory was issued after the release as a precaution until laboratory testing could be completed (Montana Fish, Wildlife, and Parks 2011a). Fillet tissues were tested to reflect potential effects on human health from fish consumption. No petroleum hydrocarbons or oil residues were detected in any of the samples (Montana Fish, Wildlife, and Parks 2011b).

***Sundre, Alberta**: On June 7, 2012 a rupture released approximately 2,900 barrels (463 m^3) of light crude oil from the Plains Midstream pipeline into the Red Deer River downstream of Sundre, Alberta (Alberta Energy Regulator [AER] 2014). The release occurred in a*

populated area at a time of high water levels (i.e., flow in Red Deer River was ten times seasonal flow) and affected landowners and businesses more than 25 miles (40 km) downstream of the release (AER 2014).

Air monitoring, including a monitor near the release location, was initiated on June 8, 2012 and continued while clean-up activities progressed. No hydrogen sulfide or other air quality issues were detected, and no exceedances of the provincial ambient air quality objectives were reported at any time during clean-up activities (AER 2014).

Water quality monitoring of drinking water samples reported hydrocarbon concentrations below applicable guidelines (Teichreb 2014).

***Mayflower, Arkansas**: On March 29, 2013, a breach released approximately 3,190 barrels of heavy crude oil from the ExxonMobil pipeline into a residential area, resulting in the evacuation of 22 homes (ADEQ 2013a; NAS 2015). Response crews were on site within 30 minutes of detection of the release (ADEQ 2013a). Air quality monitoring in residential areas on the days after the release reported that benzene concentrations were below detection (0.05 ppm) (ADEQ 2013b). VOC concentrations of up to 29 ppm were reported on the day of the release, but had diminished to 0.2 ppm by April 2, 2013 (ADEQ 2013b). Higher levels of both benzene and VOCs were measured in work areas, and workers wore respiratory protection as specified in the health and safety plan (ADEQ 2013b; NAS 2015).*

***Mooringsport, Louisiana**: On October 13, 2014, approximately 4,500 barrels of sweet crude oil were released from the Sunoco Logistics pipeline near Morringsport, Louisiana, affecting approximately ten miles of creek (USEPA 2014b). Although oil entered the Tete Bayou, it was prevented from entering Caddo Lake, which is used for potable water.*

Continuous air monitoring was conducted under supervision of the environmental agencies. Two households temporarily relocated; however, air monitoring results indicated that no hazards were present in populated/residential areas and that detected levels would not pose a health issue to residents (USEPA 2014b; USEPA 2014a).

***Glendive, Montana**: On January 17, 2015, a rupture of the Bridger Pipeline LLC pipeline released approximately 715 barrels (30,000 gallons) of Bakken light crude oil into the Yellowstone River, approximately 5 miles upstream of Glendive, Montana (MT DEQ 2015a). At the time of the release, there was extensive ice cover, restricting recovery efforts. The City of Glendive obtains its water from the Yellowstone River.*

Soon after the release, a malodorous odor was reported to be present in the City of Glendive drinking water. As a result, the Centers for Disease Control and Prevention recommended that residents not ingest municipal water. Analysis of the water later showed elevated concentrations of VOCs, predominantly benzene exceeded the

drinking water standard of 5 ppb (MT DEQ 2015c). Despite these elevated concentrations, additional sampling and analysis of the municipal water resulted in the water supply being declared safe to drink on January 22, 2015 (i.e., one week after the release). During the ice-breakup in the river on March 14, 2015, monitoring equipment installed at the water treatment plant detected higher than normal levels of VOCs. The plant was subsequently shut down and a water conservation request was made to the City of Glendive. The water treatment plant completed the installation of an aeration system to treat VOCs and allow the plant to continue operating during the breakup. The conservation request was lifted on March 16 and no VOC detections have been made since (MT DEQ 2015a).

Ten groundwater wells were also sampled. The wells were selected based on their shallow depth and close proximity to the break. No VOCs were detected in any of the ten wells (MT DEQ 2015a).

Seven days of continuous ambient air monitoring in the City of Glendive during January 2015, following the release, showed non-detectable concentrations of VOCs, including benzene. As a result, scientists from the National Oceanographic and Atmospheric Administration Emergency Response Division concluded that the levels of contaminants were "…well below public health concern thresholds and may in fact be near background levels" (MT DEQ 2015a).

After the release, the Montana Department of Fish, Wildlife, and Parks issued a fish consumption advisory since it was confirmed that fish tissue samples showed detectable levels of PAHs. However, by the time the ice had left the river, the fish tissue samples showed no detectable concentrations in edible muscle tissue and the advisory was lifted (MT DEQ 2015a; Stuart 2015).

***Santa Barbara, California**: On May 19, 2015, a rupture of the Plains All American Pipeline near Santa Barbara, California resulted in the discharge of an estimated 2,400 barrels (101,000 gallons) of heavy crude oil, 480 barrels (20,000 gallons) of which is estimated to have reached the ocean near Refugio Beach (NAS 2015). The heavy crude oil was discharged from a heated transmission pipeline and comprised a blend of oils from four nearby platforms (i.e., it was a conventional heavy crude oil, not a diluted bitumen). As a result, 138 square miles of fishing grounds were closed to harvesting (Hamm 2015). To assess concentrations of oil related contaminants in seafood, the California Office of Environmental Health Hazard Assessment (OEHHA) developed a sampling and analysis plan that focused on concentrations of PAHs in mussels, but also included samples of finfish and invertebrates (OEHHA 2015). Elevated PAH concentrations were observed initially but were below levels of concern within six weeks of the release (OEHHA 2015).*

7.1.4.1.3 Expected Effects of Released Oils

The effects of released oil on human health will vary depending on both the characteristics of the released oil and ambient/meteorological conditions at the time of the release. While a number of oil characteristics may influence the fate and transport, oil chemistry is the strongest influence, affecting both the route of potential exposure and the longevity of exposure (i.e., short term or long term). Environmental characteristics include river flow and proximity of human receptors.

One important finding was that contamination of potable wells, while possible, appears unlikely. Of the case studies examined, surface releases of crude oil did not appear to affect potable wells. The Cass Lake, Minnesota case study considered a subsurface release of crude oil and determined that the groundwater plume was limited 500 ft beyond the oil source. Therefore, effects on groundwater quality (as a potential source of potable water) are unlikely where spill response is prompt and effective, and likely to be localized even where spill response is delayed or not effective.

The environmental effects associated with the type of oil, and characteristics of the environment in which a release occurs, are described in Table 7-43 and Table 7-44 respectively.

Table 7-43 Environmental Effects: Human Health

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil chemistry—volatiles	Light crude oils contain 35 to 40 wt % volatile organic compounds (≤C_{10}) (www.crudemonitor.ca) The higher percentage of volatiles increases the risk of short-term inhalation exposure relative to other oil types.	Medium crude oils contain 25 to 30 wt % volatile organic compounds (≤C_{10}) (www.crudemonitor.ca).	Heavy crude oils contain 15 to 20 wt % volatile organic compounds (≤C_{10}) (www.crudemonitor.ca). Diluted bitumens tend to have a lower proportion of light, volatile compounds than conventional heavy oils (NAS 2015). With the lowest level of volatile compounds, heavy crude oils would be expected to have the lowest risk of inhalation exposures. Although diluted bitumens have a lower proportion of light volatile compounds than other commonly transported crude oils, the level of concern with respect to health risk from inhalation is reportedly the same as other commonly transported crude oils (NAS 2015).	Although the risk of vapor inhalation varies by oil type, health effects associated with short term inhalation exposures have been reported for spills of light, medium and heavy oils, as indicated by the case studies.
Oil chemistry—TEX	The total BETX concentration of light crude oils is 2 to 4 wt % (Zhou et al. 2015). Light oil spills have affected surface drinking water supplies (see case studies for Pine River, BC and Glendive, Montana).	The total BTEX concentration of medium crude is 1 to 3 wt % (Zhou et al. 2015).	BTEX concentration of heavy crude oils, including diluted bitumens, is 0.5 to 1.5 wt % (Zhou et al. 2015).	BTEX are among the most volatile, soluble, and toxic of the crude oil components, with low thresholds for taste and odor in water. Increasing concentrations would be expected to increase potential for inhalation exposures and impacts to drinking water supplies.

Table 7-43 Environmental Effects: Human Health

Oil Characteristic	Light Crude Oil	Medium Crude Oil	Heavy Crude Oil	Other Comments
Oil chemistry—TPAH	Alberta sweet mixed blend crude oil has higher TPAH, and proportionally more naphthalenes and alkyl naphthalenes than oil sands hydrocarbons (Yang et al. 2011). Although PAHs were detected in fish muscle tissues following a light oil release (Glendive, Montana case study), this environmental effect appears to have been influenced by the presence of an ice cover and PAHs were not detected following ice break up.	Alaska north slope crude oil has higher TPAH, and proportionally more naphthalenes and alkyl naphthalenes than oil sands hydrocarbons (Fingas 2010; Yang et al. 2011). PAHs were not detected in fish tissues following a medium crude oil release (Laurel, Montana case study).	Diluted bitumens typically have similar to lower concentrations of TPAH than light and medium crude oils, although the distribution of PAHs differs. PAHs were found in fish tissues following spills of diluted bitumen (Marshall, Michigan case study) and heavy crude oil (Santa Barbara, California case study).	Total PAH levels in diluted bitumen appear to be similar to or lower than levels in light, medium and heavy conventional crude oils (Zhou et al. 2015). PAHs are the crude oil components most commonly found in fish and shellfish, as indicated by the case studies.
Oil chemistry—resins and asphaltenes	Light crude oils contain very little in the resins and asphaltenes fractions, making their lighter aliphatic and aromatic components relatively bioavailable, but also allowing for rapid biodegradation or weathering of these oils, reducing the potential for long-term (chronic) exposures.	Medium crude oils also contain relatively small fractions of resins and asphaltenes, although more than light crude oils. Medium crude oils also have good potential for biodegradation in the environment.	Heavy crude oils, and diluted bitumens in particular, contain large amounts of resins and asphaltenes. While these fractions are generally insoluble in water and thus non-toxic, they are slow to degrade and can act as reservoirs for the slow release of other more toxic hydrocarbon constituents such as PAHs.	Resins and asphaltenes comprise the "heavy" end of crude oils, and diluted bitumens are proportionally richer in these components than light or medium crudes.

Table 7-44 Environmental Effects: Human Health

Environment Characteristic	Low	Medium	High	Other Comments
Distance to human receptors	The potential for inhalation exposures to the general public are greatest near the release site and in areas of oil recovery activities. These exposures may result in residents leaving their homes (e.g., Burnaby, British Columbia, Marshall, Michigan, and Mayflower, Arkansas case studies). Occupants typically return to their homes within a few days to a few weeks. Reported health effects from oil spills in populated areas (such as Burnaby, British Columbia, Salt Lake City, Utah, and Marshall, Michigan case studies) included headaches, eye and respiratory irritation, and nausea.	N/A	Air monitoring performed in Glendive, Montana (five miles upstream of a release) did not detect VOC or benzene in the air at levels that would represent a health concern following the release (Glendive, Montana case study).	Although toxicological effects from short-term chemical exposure are associated with distance of human receptors from released oil, other health effects, such as anxiety and depression, may be more strongly related with an individual's perceived risk regardless of whether the individual was physically exposed (Eykelbosh 2014).
River flow	Rivers with low flow are more likely to experience laminar flow and lower velocities, reducing the opportunities for mixing and the length of watercourse exposed to oil (e.g., Mooringsport, Louisiana case study).	Rivers with moderate flows will transport oil downstream and mixing could cause dispersion or submersion of oil.	Rivers with high flows can transport oil rapidly downstream and laterally onto floodplains (e.g., Marshall, Michigan case study; Laurel, Montana case study; and Red Deer River, Alberta case study).	The further the oil is transported downstream, and the more turbulent the flow conditions, the greater the likelihood of public exposures via inhalation of VOCs and BTEX from oil and direct contact with oiled shorelines and sediment. Long-distance transport would also increase the likelihood for potable water intakes to be reached and potentially affected.

Table 7-44 Environmental Effects: Human Health

Environment Characteristic	Low	Medium	High	Other Comments
Seasonal temperature	Low ambient temperatures may reduce the rate of evaporation of VOCs in spilled crude oil. However, low temperatures may also be accompanied by "inversion" conditions in low-lying areas, reducing the rate of dispersion for vapors in air. Ice cover may restrict the amount of volatilization of the BTEX components of the oil, increasing the presence of these compounds in water (e.g. Glendive, Montana case study).	N/A	High ambient temperatures could theoretically lead to localized increases in volatile concentrations. However, "inversion" conditions are less likely and atmospheric stability is usually lower at warm temperatures, resulting in more rapid dispersion of vapors in air.	Prediction of hydrocarbon vapor concentrations in air is complex, depending upon multiple factors. Spatial heterogeneity is likely to be high. Localized exposure to high concentrations of hydrocarbon vapors in air is possible for any release, however, such exposures would be indicated by strong odors making it likely that individuals would become aware of their exposure and respond accordingly.

7.1.4.2 Land Resource Use

7.1.4.2.1 Description

Releases of oil and the subsequent activities related to clean-up and remediation have the potential to disrupt normal land and resource use activities. The nature and duration of the effects will depend on the setting and the types of land and resource use activities that could be affected. Depending on the setting, an accidental release of oil can result in injury or loss of life, short- or long-term evacuation of people living or working in the area, temporary closures of water treatment facilities and other infrastructure (including roads), and suspension of activities in outdoor parks, and recreational areas and facilities.

Land and resource use activities can also be adversely affected by oil releases as a result of closures, suspensions or other constraints on these activities that remain in place until clean-up and remediation activities have been completed and response authorities have determined that conditions are safe for resumption of land and resource activities. Examples of land and resource uses and associated activities that may be adversely affected by an accidental oil release include agricultural lands, aquaculture resources (including the harvesting of wild rice), recreational or commercial fishing, forestry and other industrial activities, outdoor recreation activities (e.g., boating, swimming, hiking, biking), recreational facilities such as parks and historical or cultural sites, and cultural use of resources (use by indigenous peoples).

7.1.4.2.2 Observed Effects

The following sections provide examples of instances where accidental releases of oil have adversely affected land and resource use activities and describe the nature and extent of those effects.

Accidental releases of oil can lead to loss of life and injuries for people engaged in land and resource use activities in proximity to the release site, particularly in cases where the oil ignites. There are relatively few situations where oil releases lead to loss of life or injury, and most of these involve accidental releases caused by construction or repair activities, typically involving refined products or light oils. For example, in 2010, two people working to repair an Enbridge pipeline at a location near Clearbrook, Minnesota were killed when leaking oil ignited (Bloomberg News 2010). In 2005, a bulldozer operator working near Lufkin, Texas was injured after he accidentally struck a crude oil pipeline operated by Sunoco Pipeline L.P.; the released oil ignited (ProPublica 2005). Near Walnut Creek, California, five workers were killed and another four were injured in 2004 when contractors accidentally struck a Kinder Morgan Energy Pipeline Partners pipeline carrying gasoline (Office of the State Fire Marshall 2004).

Accidental oil releases in populated areas and potential for adverse effects on health and safety can lead to evacuation of nearby residents or workers. The Westridge release in Burnaby British Columbia occurred in 2007 and resulted in approximately 1,500 barrels (240 m^3) of heavy synthetic crude oil being released as a result of damage to a pipeline. This resulted in 50 homes being evacuated for several nights (CBC News 2007) and residents of five houses being evacuated for four months or more until clean-up operations were completed (Raptis 2011). The

2010 Marshall pipe rupture, where 20,082 barrels (3,193 m^3) of crude oil were accidentally released and a substantial portion entered the Kalamazoo River, resulted in six houses being evacuated on the day after the release due to concerns about odor (NTSB 2012b). A voluntary evacuation notice was issued to about 50 homes four days after the release and were not lifted until 18 days after the release occurred (NTSB 2012b). In these cases, the evacuations were issued due to concerns related to public health and safety resulting from direct contact with oil (see Section 6.1.5.1).

Evacuations have also occurred when oil releases have occurred in rural settings. In 2011, the rupture of ExxonMobil's Silvertip Pipeline near Billings, Montana resulted in crude oil entering the Yellowstone River. Due to fears about a possible explosion, 140 residents of the community of Laurel were evacuated for about four hours until fumes had dissipated (O'Connor 2011). The release of crude oil from ExxonMobil's Pegasus Pipeline at a location near Mayflower, Arkansas in 2013 resulted in more than 20 homes being evacuated due to fumes and fire hazard. One year after the release, residents claimed to continue to have adverse health effects from the release (rt.com 2014).

In the case of the 2005 Lake Wabamun release in Alberta, where approximately 4,500 barrels of Bunker C fuel oil (Heavy Fuel Oil 7102) and 550 barrels of Pole Treating Oil were released as a result of a train derailment, local residents were evacuated 30 minutes after the release but were allowed back to their homes later that same day (Lake Wabamun Residents Committee 2007). As a result of the 2002 Cohasset release, 6,000 barrels of crude oil (954 m^3) were released in forested-shrub-scrub wetland in Minnesota. Potentially affected land owners were contacted immediately, and seven residents were evacuated for a period of 24 hours while 11 acres of the affected land were burned to prevent the oil from reaching the Mississippi River (NTSB 2004).

Odors associated with the 2011 Plains Midstream Canada Rainbow pipeline release in northern Alberta (approximately 28,000 barrels of crude oil) were identified as the reason for suspension of classes at the Little Buffalo School on Lubicon Cree First Nation in Cadotte Lake (Henton 2011).

Accidental releases of oil have adversely affected municipal and residential water supplies, including surface water and groundwater. In 2000, 6,200 barrels (986 m^3) of oil entered the Pine River upstream of the Town of Chetwynd, British Columbia and resulted in Chetwynd shutting down its water withdrawals from the river following the release due to concerns about oil contamination of the water supply (BC MOE 2000c). As a consequence, the Town developed an alternate water supply using groundwater (Green 2000).

Only July 29, 2010, 4 days after the Enbridge Line 6B release in Marshall, Michigan, the Calhoun County Health Department issued a precautionary Bottle Water Advisory to allow time for well water sampled to be collected and analyzed for possible contamination from the release (MI DCH 2013). Wells located more than 200 ft from the high water mark of the flood event, which included most of the municipal wells in the area, were not expected to be a risk of

contamination. The Bottled Water Advisory remained in effect until November 8, 2010 (MI DCH 2013), 105 days after the release occurred.

Following the Lake Wabamun release, the local health authority advised all residents not to use lake water for drinking purposes but advised that lake water could be used for recreational purposes (CAW/TCA 2006). The ban on use of lake water for drinking was still in place one year after the release but testing at that time determined that lake water no longer represented a threat to human health (Edmonton Journal 2007).

As a result of the Silvertip pipeline release into the Yellowstone River, the City of Billings and the community of Lockwood closed their municipal water intakes as a precautionary measure for a couple of hours after the release (Ritter 2011). Another release on the Yellowstone River in 2015 from the Bridger Pipeline resulted in the community of Glendive, Montana being unable to use water from the river for six days, with residents having to rely on bottled water (Lutey 2015; USEPA 2015a).

Accidental releases of oil have also adversely affected urban infrastructure, other than water and industrial intakes. For example, the 2007 Westridge release in Burnaby caused a section of the Barnett Highway to be closed for several days after the release (CBC News 2007).

Some of the best documented effects of oil releases on land and resource use relate to impacts on recreational resources and activities, notably beach activities and fishing. The nature of effects, such as the closure of recreational facilities (e.g., beaches) and the implementation of advisories related to swimming, boating, and fishing are usually well documented for releases in the United States because such damages are a key element of the NRDA process. Some examples of release effects on recreational resources and activities include:

- In 1996, heavy oil released from a pipeline owned by Chevron Industries into Pearl Harbor, Hawaii resulted in the USS Arizona Memorial and visitors' center being closed due to odors from the release (Kakesako et al. 1996). The visitors center was closed for four days following the release, which also resulted in closure of nearby bicycle/jogging paths for two weeks due to clean-up activities and the closure of Pearl Harbor to vessel traffic and recreational and commercial fishing and boating (Natural Resources Trustees for Pearl Harbor, Oahu, Hawaii 1999).
- The Red Butte Creek oil release resulted in the immediate closure of the creek and nearby parks, portions of which were still closed 40 days after the release (Salt Lake City no date), with clean-up operations being adjusted to accommodate two important holiday events. Red Butte Creek was declared safe for regular use by local residents two years after the release occurred (O'Donoghue 2012).
- As a result of the Marshall release, county health agencies closed 39 miles of the river system to the public for reasons of health and safety. Parts of the river were opened for public use 21 months after the event, and a Fish Consumption Advisory and a swimming advisory were also lifted at that time. Small sections of the river were subsequently closed to recreational activities for short periods of time during the following two years to allow reclamation and restoration activities to be completed (USFWS et al. 2015b).

- As a result of the Lake Wabamun release, parts of the lake were closed to swimming and boating for nearly one year, and a fish and waterfowl consumption advisory for the lake remained in place for another two years (Sherwood Park News 2008).
- Oil from the Westridge release resulted in the closure of Cates Park in North Vancouver (Woodward 2007). Some beaches were closed for 4 months after the release, and 15 kilometers of beaches eventually required remediation (Canada.com 2007b).
- The 2013 release of 600 barrels of diesel fuel (80 m^3) from a pipeline adjacent to Willard Bay, a reservoir connected to the Great Salt Lake, caused closure of some facilities in Willard Bay State Park for a period of four months (O'Donoghue and Cabrero 2013).
- In 2015, crude oil from a break in a pipeline owned by Plains All American Pipeline released into the Pacific Ocean at a location north of Santa Barbara, California (NOAA Office of Restoration 2015) and resulted in the closure of two California State Beaches for a period of up to two months (Panzar 2015).

Accidental releases of oil can adversely affect agricultural land use. In 2013, 20,600 barrels of crude oil (3,227 m^3) leaked from a Tesoro Logistics pipeline in North Dakota in the middle of a farmer's field. The affected landowner indicated that it would likely take two to three years of cleaning up the release before agricultural activities could resume and that there would be negotiations for compensation (FoxNews 2013). Clean-up activities were still underway in 2014 and, at that time, Tesoro Corp estimated that it would be another year before clean-up activities would be complete (Associated Press 2014b).

In the case of the 2008 Mt. Erie pipeline release, about 5,000 barrels (795 m^3) of crude oil affected agricultural and forested lands, and the responsible party eventually purchased 157 acres of agricultural land in the release zone (Arcadis 2011). For the Marshall release, the Michigan Department of Agriculture issued a ban on surface water withdrawals for crop or lawn irrigation, or livestock watering (NTSB 2012b). With the release from the Silvertip Pipeline occurring while the Yellowstone River was in flood, some of the released oil was deposited on cropland and pasture-land along the river (Fox News.com 2011). For the Silvertip pipeline release, farmers were advised not to use water from the river for irrigation or for stock watering (Ritter 2011). More recently, in 2015 a farmer near the Manitoba-Saskatchewan border discovered that 500 barrels (79 m^3) of oil had leaked from a Tundra Oil and Gas pipeline onto his farmland, but there is no information on the extent of damages to his agricultural operations (Dyck 2015).

Accidental releases of oil can affect industrial activities, particularly in situations where released oil enters water bodies that are used as an industrial water source.

The Wabamun release resulted in a thermal power plant having to shut down for about 40 days due to contamination of lake water that was being used to produce steam (TransAlta 2005). Clean-up operations associated with Westridge release resulted in closure of parts of Burrard Inlet for shipping and caused Shell Canada's refinery to cease operating for 11 days (Canada.com 2008).

When over 6,000 barrels of heavy Venezuelan crude oil released from the Athos I tanker entered the Delaware River in 2004, two reactors at the Salem Nuclear Power Plant were closed down for

10 days, and the Port of Philadelphia was shut down for three days (NOAA Office of Response and Restoration 2014; University of Delaware 2004;). Compensation for closing the nuclear power facilities was determined to be $33.1 million (NOAA Office of Response and Restoration 2014).

There are likely many more examples of these effects, but the details are seldom made public because claims for damages are negotiated directly between the responsible and affected parties, and the terms of the settlements are never made public.

While an accidental release of oil may affect land and resource use by Indigenous People (Canada) and Native American tribes (United States), the nature of these effects has not been well documented or reported. Where tribes and First Nations have legally established rights to harvest affected resources, responsible parties may negotiate settlements with affected parties and the terms of the settlement, including the nature and extent of damages, are not usually disclosed to the public. In the case of the Lake Wabamun release, the Paul First Nation initiated lawsuits for damages to lands and resources, as well as the effect to the residents' way of life, and ultimately received a settlement of $10 million (CBC News 2008). Under United States regulations, Indian tribes can be included as Trustees in the NRDA process when natural resources under their jurisdiction are injured (OPA 1990; 33 U.S.C. 2706b). Although tribes face multiple barriers to participation in the NRDA process (Hildreth 2011), there are some examples where tribes have been designated as trustees in an NRDA process. For example, the Nottawaseppi Huron Band of the Potawatomi Tribe (the Huron Tribe) and the Match-E-Be-Nash-She-Wish Band of the Pottawatomi Indians (the Gun Lake Tribe) were trustees involved in the NRDA process for the Marshall release (USFWS 2015b). However, in the case of the NRDA conducted for the Buzzard's Bay Oil release, the Wampanoag Tribe of Gay Head (the Aquinnah) reached a separate settlement with the Responsible Party and was not part of the final agreement (NOAA et al. 2014).

7.1.4.2.3 Expected Effects of Oil Releases

There are four factors that help determine the nature and magnitude of land and resource effects associated with an accidental petroleum release.

- The intensity of land and resource use and the potential for adversely affecting large numbers of people. Releases in densely populated or intensively used areas tend to have larger effects than releases in rural or unpopulated areas. Similarly, releases can potentially affect large numbers of people where they affect water intakes, other public infrastructure, or areas or facilities that are used for recreational or cultural purposes.
- Whether the release can be contained on land or whether the oil is able to enter a waterbody, especially a moving water body. With oil being able to spread more easily on water than on land, accidental releases into water are likely to affect a larger area and potentially affect a greater number and types of land and resource uses. The effects on land and resource use that result when a release enters a creek, river, or lake are likely to be much greater in magnitude than a release restricted to land.
- The season during which the release occurs. Releases during winter months tend to be less severe and easier to manage. Cold weather makes released oil more viscous, so it is less likely to spread and easier to contain. Also, if the surface water and ground is frozen,

released oil is less likely to spread or penetrate below frozen surfaces, so it is easier to contain and recover. However, releases from underwater pipelines in winter may present real challenges to oil collection because oil may pool underneath ice.

- The duration and invasiveness of clean-up and restoration activities. Oils that are more volatile might have a greater short-term effect (combustion leading to risk to life or odor and volatility issues leading to evacuation) but, in the longer term, may be easier to clean-up such that recovery occurs more quickly. Heavy oils, especially if they enter a water body during the summer months, tend to be more difficult to clean-up. As was observed in the case of the Marshall release, the released oil affected at least 39 miles of river bed and shoreline, and it took considerable time and effort for reclamation and restoration activities to be completed.

Table 7-45 summarizes how these factors may affect the duration and magnitude of the effects of an accidental oil release on different types of land and resource uses. In all cases, the extent of the effects will also be highly dependent on the duration of clean-up and remediation activities and the time required before response authorities have determined that land and resource use activities can be safely resumed.

Table 7-45 Summary of Expected Effects of Oil Releases on Land and Resource Uses

Effect	Oil Properties	Setting (Land/Water)	Season of Release
Loss of life and injuries	Lighter oils have greater potential for combustion	Oil releases on or in water may quickly spread and release volatile, explosive compounds, especially for lighter oils during warm seasons	Releases in winter have lower potential for effect
Evacuation	Lighter oils have greater potential for odors that cause evacuation	Oil releases on or in water may quickly spread and release volatile, explosive compounds, especially for lighter oils during warm seasons	Releases in winter have lower potential for effect
Public water supplies and other infrastructure	Lighter oils have potential for short-term effect but heavier oils may have long-term effect	Oil releases on or in water have very high potential for long-term effect	Releases in winter have lower potential for effect
Recreation	Lighter oils have potential for short-term effect but heavier oils may have long-term effect due to clean-up activities	Oil releases on or in water have very high potential to affect a greater area and to have long-term effect associated with clean-up activities	Releases in winter have lower potential for long-term effects and will affect fewer users
Agriculture	Lighter oils have potential for short-term effect but heavier oils may have long-term effect due to clean-up activities	Oil releases on or in water have higher potential to affect a greater area while releases on land may require long-term clean-up.	Releases in winter have lower potential for long-term effects and will affect fewer users

Table 7-45 Summary of Expected Effects of Oil Releases on Land and Resource Uses

Effect	Oil Properties	Setting (Land/Water)	Season of Release
Industrial activities	Lighter oils have potential for short-term effect but heavier oils may have long-term effect	Oil releases on or in water have very high potential to affect a greater number of users	Releases in winter have lower potential for long-term effects and will affect fewer users
Cultural Activities	Lighter oils have potential for short-term effect but heavier oils may have long-term effect due to clean-up activities	Oil releases on or in water have very high potential to affect a greater area and to have long-term effect associated with clean-up activities.	Releases in winter have lower potential for long-term effects and will affect fewer users

7.2 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL NEAR MOSQUITO CREEK

The proposed pipeline is expected to pass approximately 2,000 ft northeast of the head of Mosquito Creek. Mosquito Creek flows into Lower Rice Lake, which is located on tribal lands of the White Earth Reservation, and is a growing area for wild rice. Therefore, the potential for overland flow of crude oil from the release area to Mosquito Creek, and subsequent transport down Mosquito Creek to Lower Rice Lake, was investigated. The hypothetical release location is in a relatively flat forested area that gently slopes toward a homestead and agricultural and grassland habitats. The overland flow path is approximately 0.6 miles long. Agricultural drainage ditches provide a preferential flow path towards Mosquito Creek, and sections of the creek also have been channelized. Thus, Mosquito Creek can be described as a semi-natural watercourse that ranges in width from approximately 3 to 30 ft as it flows approximately 11.75 miles to the south and west before entering Lower Rice Lake. As identified in Chapter 3, Mosquito Creek is part of the Mosquito Creek Wildlife Management Area (WMA) located in the Chippewa Plains Subsection of the Northern Minnesota Drift and Lake Plains Section of the greater Laurentian Mixed Forest Province (MN DNR 2016b; MN DNR 2016c). Land cover is predominantly forest (57%) and is dominated by aspen (MN DNR 2006).

7.2.1 Description of the Freshwater Environment

At its origin, Mosquito Creek is a narrow ditch or swale (Figure 7-2). As it grows to around 30 ft in width, Mosquito Creek flows through marshy grassland and riparian bog (occasionally treed), passing through agricultural land and nature preserves before entering Lower Rice Lake. The average velocity of the Mosquito Creek changes with season, with slowest velocities (e.g., about 0.52 ft per second) expected during low flow periods in the winter, and greater velocities (e.g., about 3 ft per second) during the spring high flow period. Mosquito Creek enters Lower Rice Lake at its north end, about 0.4 miles from the lake outflow, also at the north end. A non-vegetated channel between the inflow and outflow indicates that much of the creek flow is likely to bypass the lake and report directly to the outflow. A water level control structure is

located approximately 0.64 miles downstream from the lake outflow. Lower Rice Lake is approximately 0.5 to 1 mile wide and 4.2 miles long.

Recreation, tourism and forestry are the major land uses in the area of Mosquito Creek and Lower Rice Lake (MN DNR 2016b). Although much of the land is agricultural (grassland), it does not appear to be under intensive use. Deer, bear, waterfowl, and migratory species offer hunting and trapping opportunities (MN DNR 2006; MN DNR 2016b). Being part of the Chippewa Plains, Mosquito Creek is known or expected to be home to 83 Species in Greatest Conservation Need (SGCN); these include birds (60 species), fish (4 species), insects (8 species), mammals (6 species), mollusks (2 species), and reptiles (2 species) (MN DNR 2006). Of these, 22 species are afforded federal or state endangered, threatened, or of special concern status (MN DNR 2006; MN DNR 2016d). It is foreseeable that some of these SGCN could utilize aquatic habitats along the Mosquito Creek. The area around Mosquito Creek and Lower Rice Lake is shared by White Earth Reservation, private owners, and DNR Forestry Trust lands and is populated with summer homes and Native American communities (White Earth, Pine Point/Ponsford, Naytahwaush, Elbow Lake, and Rice Lake [IAC 2012]). The Mosquito Creek WMA is complex of forest, agricultural lands and 24 emergent wetlands (MN DNR 2016b). The lower section of Mosquito Creek enters White Earth Reservation, which surrounds Lower Rice Lake (known for wild rice), and is directly downstream of the hypothetical release location.

Several access points downstream from the proposed pipeline crossing location were visited in May, 2016, to provide additional insight into baseline environmental conditions for Mosquito Creek and surrounding environments. Representative site photographs are provided in Figure 7-2 through Figure 7-5. Field observations are summarized in Table 7-46.

Figure 7-3 Mosquito Creek and Habitat Approximately 2 Miles Downstream of the Pipeline Crossing Looking Downstream

Figure 7-4 **Mosquito Creek and Riparian Habitat Approximately 25 Miles Downstream of the Pipeline Crossing to the West of Lower Rice Lake**

Figure 7-5 **Mosquito Creek and Riparian Habitat Approximately 55 Miles Downstream of the Pipeline Crossing to the West of Lower Rice Lake**

Table 7-46 Environmental Characteristics Observed at Selected Access Points on the Mosquito Creek in May, 2016

Access Point	Latitude Longitude	Notes
211th Avenue and Mosquito Creek approximately 2 miles downstream of pipeline crossing	47.4479 -95.3396	*Habitat Description:* both sides of road are cattle pasture and nearly level. There was no water flowing in the shallow, excavated ditch (Mosquito Creek) at the time of the field visit. An approximately 36-inch CMP culvert is under road here. Dominant vegetation is nonnative, cool season pasture grasses, with scattered small patches and groves of bur oak/aspen trees. *Wildlife observed:* bobolink, yellowthroat, ruby-throated hummingbird, gray tree frog.
County State Aid Highway 4 and Mosquito Creek approximately 25 miles downstream of pipeline crossing	47.3873 -95.6367	*Habitat Description:* this segment has a broad floodplain with a mix of shrub swamp, wet/sedge meadow and lesser amounts of wet/aspen stands on slightly higher ground. The stream has good water clarity and abundant wild celery (*Vallisneria americana*). *Wildlife observed:* barn swallow, yellow warbler, American toad, yellow throat.
Creek 132 Road and Mosquito Creek approximately 50 miles downstream of pipeline crossing	47.35421 -95.76347	*Habitat Description:* this area has a relatively narrow stream corridor amid irregular, rolling hills (glacial moraine topography). The stream has riffles and pools, as well as a relatively narrow floodplain. The invasive, nonnative reed canary grass is codominant with native plants along stream margins. The dominant vegetation in stream buffer areas is lowland hardwood forest and mesic hardwood (oak) forest with good plant species richness/quality. *Wildlife observed:* veery, yellow throat, catbird, flycatcher, hairy woodpecker *Fish & Wildlife likely to occur in vicinity:* creek chub, smallmouth bass (personal communication from angler).

7.2.2 High Consequence Area Assessment for the Mosquito Creek to Lower Rice Lake Scenario

As defined in Section 7.0, HCAs include populated areas, drinking water source areas, ecologically sensitive areas, and commercially navigable waterways. Sensitive AOIs include Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks).

While environmentally sensitive and populated HCAs are present near the confluence of Mosquito Creek and Lower Rice Lake, modeling demonstrated that neither Bakken crude oil nor CLB floating on the surface would reach these areas under any of the seasonal flow conditions (Figure 7-6). However, AOIs are present along Mosquito Creek (Table 7-47). The locations of the HCAs and AOIs are shown in Figure 7-6.

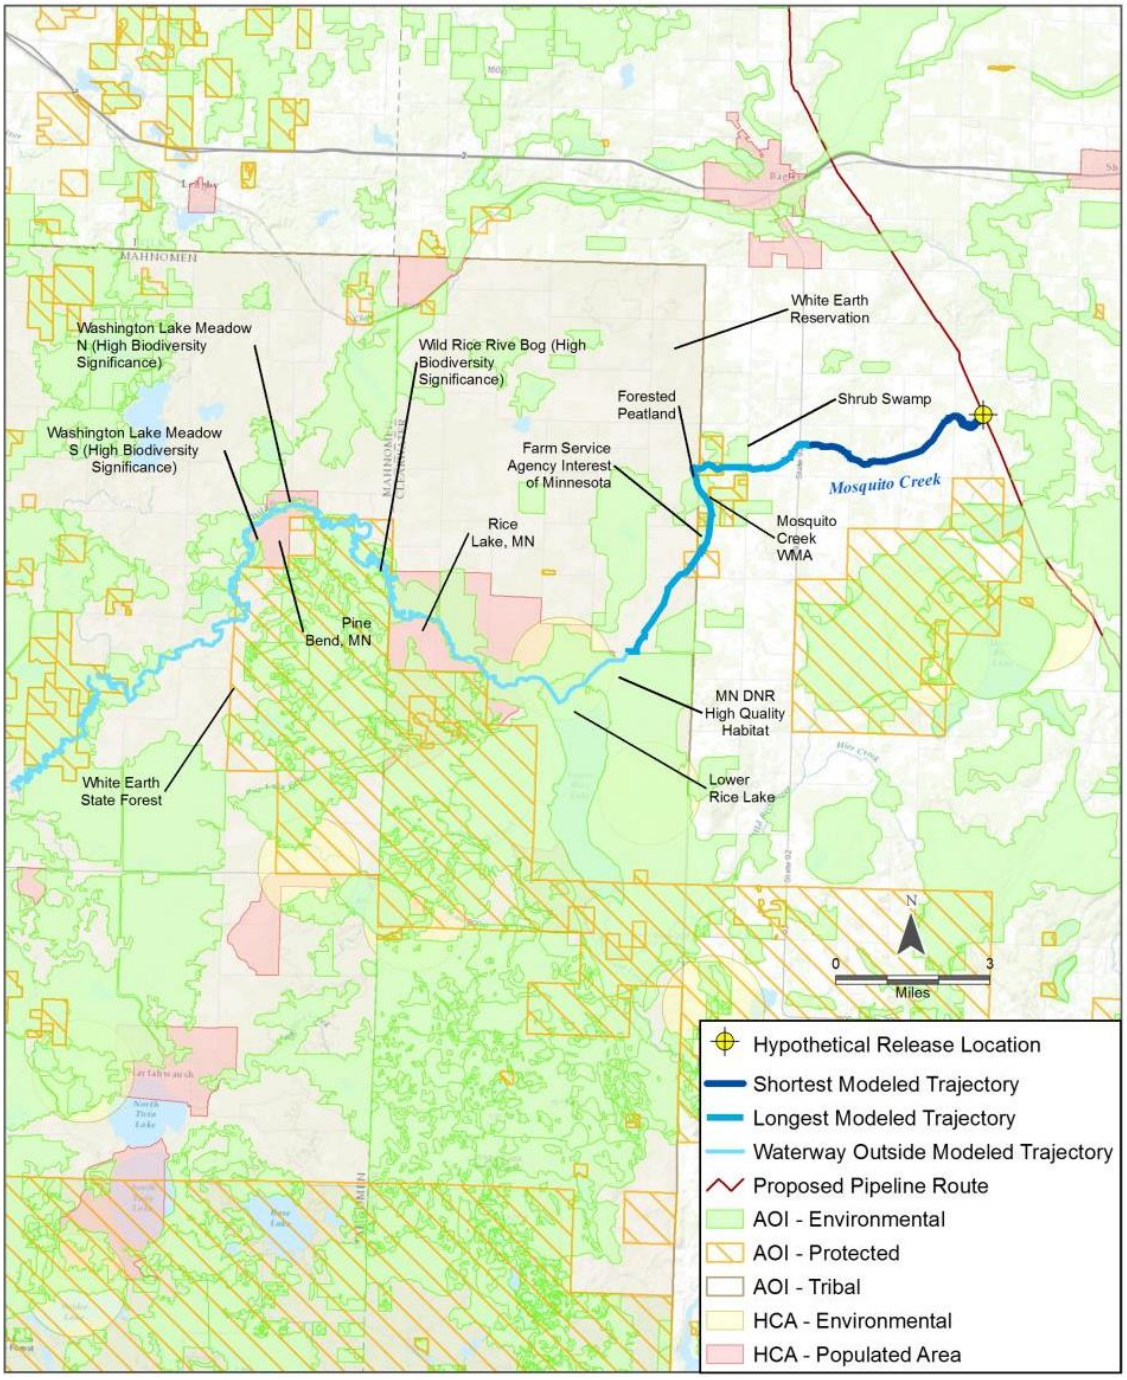

Figure 7-6 HCAs and AOIs Potentially Affected by a Crude Oil Release near Mosquito Creek

Table 7-47 Areas of Interest Potentially Affected by a Release of CLB and Bakken Crude Oil at the Mosquito Creek to Lower Rice Lake Scenario

AOI Type	AOI Subtype	Description / Locations
Environmental	Native Plant Community (Candidate)	Forested Peatland, Shrub Swamp, Tribal Lands
Protected Area	Farm Service Agency Interest of Minnesota	N/A
	Wildlife Management Area	Mosquito Creek WMA
Tribal Lands	N/A	White Earth Reservation
NOTE: Data for the AOI analysis were derived from multiple datasets provided on the Minnesota Geospatial Commons website, USGS Protected Areas Database of the United States and the Minnesota Department of Transportation.		

7.2.3 Selection of Key Ecological and Human Environment Receptors for Mosquito Creek to Lower Rice Lake Scenario

Taking into account the environmental characteristics of Mosquito Creek and Lower Rice Lake, the potential interactions of released crude oil with key ecological and human environment receptors were screened to identify key receptors for the subsequent environmental effects analysis. The rationale and results of this screening step are provided in Table 7-48.

Table 7-48 Key Ecological and Human Environment Receptors for the Mosquito Creek to Lower Rice Lake Scenario

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mosquito Creek to Lower Rice Lake Scenario	Selected (Y/N)
Terrestrial Receptors		
Soils	Low. An assumption made in the fate modeling for this scenario is that released oil in spring and summer-fall conditions would flow approximately 0.6 miles overland before reaching the channel of Mosquito Creek. After reaching the creek, crude oil could be transported downstream following a defined channel. Under winter conditions, the released crude oil is not predicted to reach the creek, but could be retained by snowpack over frozen ground. It is assumed that oil that remained on land would be physically remediated to established standards.	N
Groundwater	Low. In the event of an actual oil release, effects on groundwater quality after cleanup would be localized and/or negligible.	N

Table 7-48 Key Ecological and Human Environment Receptors for the Mosquito Creek to Lower Rice Lake Scenario

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mosquito Creek to Lower Rice Lake Scenario	Selected (Y/N)
Terrestrial Vegetation	Low. An assumption made in the fate modeling for this scenario is that released oil in spring and summer-fall conditions could flow approximately 0.6 miles overland before reaching the channel of Mosquito Creek. After reaching the creek, crude oil could be transported downstream following a defined channel. Under winter conditions the released crude oil is not predicted to reach the creek, but could be retained by snowpack over frozen ground. It is assumed that oil that remained on land would be physically remediated to established standards. Terrestrial vegetation communities along the flow path would be killed or impaired, but this area would be remediated, and vegetative cover would be restored as part of the cleanup process.	N
Aquatic Receptors		
River (Mosquito Creek)	High. An assumption made in the fate modeling for this scenario is that oil released under spring or summer-fall conditions could reach Mosquito Creek via overland flow, with subsequent physical transport downstream.	Y
Lake (Lower Rice Lake)	Medium. An assumption made in the fate modeling for this scenario is that oil released under spring or summer-fall conditions could reach Mosquito Creek via overland flow, with subsequent physical transport downstream towards Lower Rice Lake. While none of the simulations indicated that floating oil would reach the lake within 24 hours, this receptor was included in the assessment due to the importance of the area to Native Americans and local residents.	Y
Sediment	High. An assumption made in the fate modeling for this scenario is that oil released under spring or summer-fall conditions could reach Mosquito Creek via overland flow, with subsequent physical transport downstream. This allows potential interaction and/or deposition of crude oil residues to sediments.	Y
Shoreline and Riparian Areas	High. An assumption made in the fate modeling for this scenario is that oil released under spring or summer-fall conditions could reach Mosquito Creek via overland flow, with subsequent physical transport downstream. This allows potential interaction with shoreline and riparian habitat.	Y
Wetlands	High. An assumption made in the fate modeling for this scenario is that oil released under spring or summer-fall conditions could reach Mosquito Creek via overland flow, with subsequent physical transport downstream. This allows for potential interaction with riparian wetlands, and wetlands associated with Lower Rice Lake.	Y
Aquatic Plants	High. Mosquito Creek supports aquatic plant communities.	Y
Benthic Invertebrates	High. Mosquito Creek and Lower Rice Lake support benthic invertebrate communities.	Y
Fish	High. Mosquito Creek and Lower Rice Lake support fish communities.	Y
Semi-Aquatic Wildlife Receptors		

Table 7-48 Key Ecological and Human Environment Receptors for the Mosquito Creek to Lower Rice Lake Scenario

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mosquito Creek to Lower Rice Lake Scenario	Selected (Y/N)
Amphibians and Reptiles	High. Mosquito Creek and Lower Rice Lake support amphibians and reptiles.	Y
Birds	High. Mosquito Creek and Lower Rice Lake support waterfowl and other birds.	Y
Semi-aquatic Mammals	High. Mosquito Creek and Lower Rice Lake support semi-aquatic mammals.	Y
Human and Socio-Economic Receptors		
Air Quality	High. The Mosquito Creek and Lower Rice Lake area is shared by White Earth Reservation, private land owners, and MN DNR Forestry Trust lands. Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns.	Y
Human Receptors	High. The Mosquito Creek and Lower Rice Lake area is shared by White Earth Reservation, private land owners, and MN DNR Forestry Trust lands. Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health.	Y
Public Use of Natural Resources	High. The Mosquito Creek and Lower Rice Lake area is shared by White Earth Reservation, private land owners, Mosquito Creek WMA and MN DNR Forestry Trust lands. Effects on air and water quality, or the presence of crude oil residues in the sediment, riparian or wetland habitat, could potentially disrupt public use of natural resources (e.g., wild rice harvest, drinking water supplies, hunting, fishing, recreation).	Y

7.2.4 Modeled Conditions at the Release Location

A description of key modeling assumptions for the environmental effects analysis for the Mosquito Creek to Lower Rice Lake scenario is provided in this section. The OILMAP Land software was used by RPS ASA to simulate hypothetical releases of CLB and Bakken crude oils into Mosquito Creek and the flow of oil over land (Chapter 5.0) for a 24 hour period. A longer time period was not modeled as it was assumed that emergency response measures to prevent further downstream transport of released oil would be in place within the 24 hour period.

While OILMAP Land does provide an indication of the overland and downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column (Chapter 5.0). The ability of the OILMAP Land model system to accurately predict overland release pathways is in large part controlled by ground cover and the vertical and horizontal resolution of the elevation grid. In this scenario, a 0.6 mile flow path of predominantly grassland/herbaceous land cover (during non-winter months) or snow/ice land cover (during winter months) extended downslope to Mosquito Creek. This is a worst-case assumption for a release of crude oil near the watercourse. In the event of an

actual release, emergency response measures to prevent further possible downstream transport of oil would be expected to be in place within several hours of the release.

Based on data obtained from weather stations (Thorhult, MN and the University of Minnesota Itasca Biological Station, MN) near the hypothetical release location, long cold winters with periods of snow cover occur between October (averaging 0.5 inch) and May (averaging 0.4 inch), with maximum average coverage in February (13.7 inches). The retention of light crude oil in snow was assumed to be 20% of the snowpack depth for the Bakken crude oil, and 40% of the snowpack depth for the heavier CLWB. Elevation data used for overland flow modeling were obtained from the MN DNR (MN DNR 2014a) and have 10 ft horizontal resolution and 0.4 inch vertical resolution.

The two crude oil types provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (CLB/CLWB, heavy diluted bitumen crude oil types having higher viscosity and density). Seasonal variations in river flow velocity, temperature, wind speed, and snow and ice cover were all considered at the release location. A summary of key variables is provided in Table 7-49.

In the event of an actual release, the downstream extents of CLB and Bakken crude oil may be more similar, and the effects of CLB may extend farther downstream than predicted, with patchy coverage.

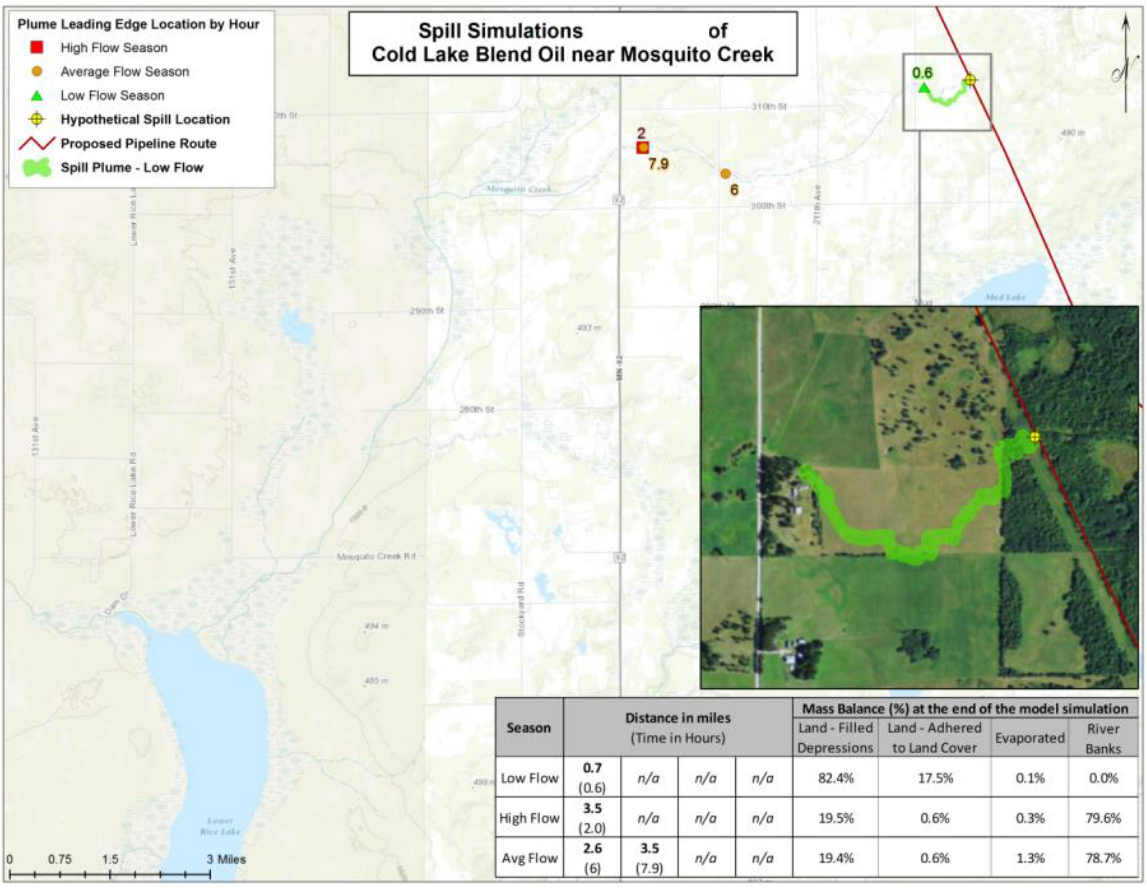
Table 7-49 Environmental and Hydrodynamic Conditions for the Three Modeled Periods at the Mosquito Creek Crossing

Season	Month	Air Temperature (°C)	Wind Speed (m/s)	Average River Velocity (m/s)
Low Flow (Winter)	February	-11.50	4.44	0.16
Average Flow (Summer)	July	19.25	3.68	0.21
High Flow (Spring)	April	4.17	4.88	1.03
NOTE: A velocity of 1 m/s is equivalent to 2.25 miles per hour.				

The highest average flow velocity of the Mosquito Creek coincides with the spring freshet (i.e., April-June), a result of rising temperatures and snowmelt. Average flow would typically occur in summer and fall seasons. July, the month with the warmest temperature, was selected to represent the maximum amount of evaporation. The lowest flow rate occurs in winter (i.e., January-March), and was typified by freezing conditions and probable ice cover on water.

The crude oil release volume was calculated as a full bore rupture, with a maximum time to response in the pipeline Control Center of 10 minutes, followed by a 3-minute period to allow for valve closure. Therefore, the release volume represents the volume of oil actively discharged in

the period of time required to detect and respond to the event (taking into consideration the pipeline diameter, pipeline shutdown time, pipeline design flow velocity), followed by the volume of oil lost due to drain-down of the elevated segments of pipeline. The maximum 13-minute response time to valve closure is an Enbridge standard for safe operations and leak detection. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown and full valve closure in the affected pipeline section. While 13 minutes is the maximum time for valve closure, this is a conservative assumption, since a response through to valve closure is expected to occur in less than 13 minutes in a full bore rupture leak scenario. Based on these assumptions, the site-specific hypothetical release volume was estimated to be of Bakken, CLB, or CLWB crude oil.



NONPUBLIC DATA HAS BEEN EXCISED

7.2.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils

A summary of the predicted downstream trajectories and mass balance for Cold Lake and Bakken crude oils, under the three seasonal scenarios, is provided in Figure 7-7 and Figure 7-8, respectively. These simulations are assumed to provide bounding conditions for a release of heavy or light crude oil types. The fate of most types of crude oil, if released, would lie within the envelope of predictions for the Cold Lake and Bakken crude oil types. The Cold Lake crude oil was assumed to be CLB for the high flow and average flow scenarios, and to be CLWB for the low flow (winter) scenario. As noted in Chapter 5.0, while OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column.

The maximum simulation duration using OILMAP Land was 24 hours, as it was assumed that emergency response measures to prevent or reduce further downstream transport of released oil would be in place within that length of time. Symbols on the drawings indicate the river seasonal flow condition (high corresponding to spring freshet, average corresponding to summer-fall conditions, and low corresponding to winter flow under ice). Numbers associated with the symbols indicate the predicted location of the leading edge of the released oil in the river after 6, 12, 18 or 24 hours. Numbers other than these (e.g., 7.9) indicate the time in hours of the predicted termination of downstream transport of the released oil due to adhesion or holdup of the oil along the river banks. Tables inserted within the Figures also provide information on the mass balance (i.e., oil remaining on the surface of the river, adhering to river banks, or evaporated to the atmosphere) of the released oil at relevant points in time after the start of the release.

[NONPUBLIC DATA HAS BEEN EXCISED...

Figure 7-8 Predicted Downstream Transport of Bakken Crude Oil at the Mosquito Creek Crossing Location

7.2.5.1 Mosquito Creek to Lower Rice Lake Release During High Flow (Spring) Period

Under the high flow scenario, CLB was predicted to travel approximately 3.5 miles downstream in Mosquito Creek, with downstream transport being terminated 2 hours after the release. This is largely a result of crude oil being held up on land (20.1%) or adhering to shorelines (79.6%). Only a small amount (0.3%) of the CLB was predicted to have evaporated to the atmosphere during that period. In the event of an actual release, emergency response measures to prevent further possible downstream transport of oil would be expected to be in place within several hours of the release.

Bakken crude oil was predicted to be transported approximately 10.4 miles downstream (or approximately 1.4 miles upstream of Lower Rice Lake), with downstream transport being

terminated within 5.3 hours of the release. After 5.3 hours, approximately 23.1% of the Bakken crude oil was predicted to have evaporated to the atmosphere, with 15.2% filling depressions on land or adhered to land cover, and the remaining 61.7% predicted to be adhering to shorelines.

The release of Bakken crude oil under high flow conditions was predicted to result in shoreline oiling nearly 3 times farther downstream in Mosquito Creek than the CLB. The difference in the extent of downstream transport was primarily due to differences in shoreline retention. Because of its higher viscosity and adhesiveness, larger amounts of CLB are predicted to strand, as a thicker layer of oil on a given length of shoreline, than for the Bakken oil. Conversely, the same amount of Bakken crude oil would affect a greater length of shoreline, with a lesser thickness of oil. This result is based on the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point was oiled to its maximum holding capacity for that oil type) as oil made its way downstream. In the event of an actual release, the downstream extents of CLB and Bakken crude oil may be more similar, and the effects of CLB may extend farther downstream than presented, with patchy coverage or partial oiling of shorelines.

A larger proportion of the Bakken crude oil was predicted to evaporate to the atmosphere than was predicted for CLB. This was due in part to the lighter and more volatile character of the Bakken crude oil. In addition, the greater downstream transport of the Bakken crude oil took more time, and resulted in more water surface area with oil, both of which would allow more of the released oil to evaporate. Volatile components of the CLB would continue to evaporate after becoming stranded on the shoreline, but this process was not included within the OILMAP Land model for stranded oil.

7.2.5.2 Mosquito Creek to Lower Rice Lake Release During Average Flow (Summer-Fall) Period

Under the average river flow condition, CLB crude oil was predicted to travel up to 2.6 and 3.5 miles downstream after 6 and 7.9 hours, respectively, at which time the leading edge of the release is predicted to be 8.3 miles upstream of Lower Rice Lake (Figure 7-7). At that time, approximately 1.3% of the CLB was predicted to have evaporated to the atmosphere, 20.0% filled depressions on land or adhered to land cover, and the remaining 78.7% was predicted to be adhering to shorelines. Emergency response measures to prevent further possible downstream transport of oil would be in place within 24 hours of the release.

Bakken crude oil was predicted to travel approximately 2.6, 5.1, 8.1 and 9.8 miles downstream after 6, 12, 18 and 21.4 hours. Downstream transport was predicted to terminate 21.4 hours after the release. By that time, approximately 36.1% of the Bakken crude oil was predicted to have evaporated to the atmosphere, 12.7% filled depressions on land or adhered to land cover, and the remaining 51.1% was predicted to be retained on shorelines. Slightly more of the released CLB crude oil was predicted to evaporate under the average river flow condition than under the high river flow condition (Figure 7-7). This difference is due largely to the warmer temperatures in the summer-fall season as compared to the spring freshet, and also due to the

greater length of time, and greater surface area of water that was predicted to be oiled during the simulation.

When compared to CLB was predicted to be transported farther downstream than Bakken crude oil. This is a result of the lower overland and shoreline oil retention values for the low viscosity Bakken crude oil, when compared to the more viscous and adhesive CLB. Although not modeled here, it is expected that a medium crude oil would exhibit fate and transport properties intermediate between those of the Bakken and CLB crude oil types, with a tendency to behave more like the Bakken crude oil. This is because the viscosity and adhesiveness properties of a medium crude oil would typically be higher but more similar to those of the Bakken crude oil, than to the CLB.

7.2.5.3 Mosquito Creek to Lower Rice Lake Release During Low Flow (Winter) Period

Under the low flow conditions of winter, it was assumed that Mosquito Creek would be frozen over (100% coverage of ice), with a layer of snow on top. Therefore, a release of CLWB from the pipeline onto land could result in a release traveling over the land surface to reach the channel of Mosquito creek, but the oil would likely pool in the dry or frozen stream channel without contacting water.

Under low flow conditions, CLWB was predicted to travel approximately 0.7 miles over the land surface, within 0.6 hours of release. At that time, approximately 82.4% of the CLWB was predicted to be held up by snow or filling depressions in the land surface, with 17.5% adhering to the land cover and only 0.1% predicted to have evaporated. A considerable amount of CLWB was predicted to adhere to the land cover and be retained in depressions along due to the high holding capacity of the snow cover. With Mosquito Creek frozen over, CLWB that reached the creek would be expected to pool in the dry stream channel, or on the surface of the ice. Little evaporation was predicted to occur under winter conditions due to low air temperature which would slow evaporation, and reduced surface area due to the predicted thick retention of CLWB on the overland flow path. Evaporation was also limited by the short (0.6 hour) duration of the simulation.

Under low flow conditions, the Bakken crude oil was predicted to travel approximately 0.7 miles over the land surface, within 0.6 hours of release. At that point, approximately 91.1% of the oil was predicted to be filling depressions in the land surface, 8.4% adhering to the land cover, and only 0.5% was predicted to have evaporated. Considerably more Bakken crude oil was predicted to adhere to land cover during low flow conditions than during high or average river flow conditions, due to the holding capacity of snow cover.

7.2.6 Qualitative EHHRA for the Mosquito Creek to Lower Rice Lake Scenario

In this section the likely environmental effects of a crude oil release at the pipeline crossing location near Mosquito Creek are described. A worst case crude oil release from a main-line pipeline, such as described here, would be an unlikely event (Chapter 4.0). The proposed

pipeline would carry a variety of crude oil types, ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumens such as CLB). Therefore, the following discussion describes the likely environmental effects of a crude oil release on relevant ecological and human environment receptors (identified in Section 7.2.3), using the predicted geographic extent of effects of released Bakken or CLB crude oil types over the 24 hour simulations as bounding conditions. Effects of season (including temperature, river flow conditions, and receptor presence/absence and sensitivity) were also considered. The rationale supporting the effects analysis, based on case studies describing the effects of crude oil releases on the various ecological and human environment receptors, was provided in Section 7.1 and Table 7-48.

7.2.6.1 Terrestrial Receptors

In spring and summer-fall seasons it is assumed that a release will flow over 0.6 miles of land downslope to Mosquito Creek, with most of the released crude oil entering the creek, rather than remaining on land. Environmental effects on soils and terrestrial vegetation are assumed to be localized to the overland flow path of the released oil. This area is limited in spatial extent, and would be remediated using conventional clean-up techniques. In the winter season it is expected that virtually all of the released crude oil would be retained in snow and fill depressions on land. This type of release would also be physically remediated using conventional clean-up techniques. The environmental effects of a crude oil release on land cover receptors are not considered further for this release scenario.

7.2.6.2 Aquatic Receptors

The aquatic environmental and ecological receptors are most closely associated with Mosquito Creek. These receptors include creek water and sediment quality, shoreline and riparian areas, wetlands, aquatic plants (including wild rice), benthic invertebrates, and fish.

If crude oil was to enter Mosquito Creek during the spring (high flow), it is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas. The distance travelled would depend upon river flow and oil type. Based on OILMAP Land simulations, light oils oil is predicted to travel father downstream than heavy oil. For heavy oil, stranding on shore would be the primary fate, with only small amounts of evaporative weathering of the oil occurring before the oil becomes stranded. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation.

The effects of crude oil releases on benthic invertebrates and fish depend on the characteristics of the released oil and environmental conditions at the time of the release. Acute toxicity to fish is commonly but not always observed in association with crude oil releases, and is an indicator that, at least briefly, concentrations of dissolved hydrocarbons (particularly mono-aromatic hydrocarbons, some low molecular weight PAHs, and short-chain aliphatic hydrocarbons) are sufficiently high to cause acute toxicity due to narcosis. Light oils have low viscosity relative to heavier oils. Turbulence in flowing water could potentially disperse light oil as small droplets in the water column, increasing the potential for toxic fractions of the light oil to dissolve into the water

column. As a result of the flow conditions, and the relatively small volume of flow in Mosquito Creek providing dilution to dissolved hydrocarbons, the potential for acute toxicity to fish and benthic invertebrates could be high, and greater for the light oil than for heavy oil.

As a headwater system, the volume of water flow associated with the spring freshet in Mosquito Creek is not likely to be sufficient to dilute and limit the maximum dissolved hydrocarbon concentration in water. Therefore, it is likely that acute toxicity to fish would occur in Mosquito Creek during spring flows, extending at least as far as the longest modeled trajectory, and potentially farther as dissolved hydrocarbons could continue to be transported downstream even when the surface oil slick has terminated. Toxicity to fish would also be more likely for the light crude oil than for the heavy crude oil due to the higher proportion of low molecular weight (and relatively water soluble) hydrocarbons in the light crude oil. The lower viscosity of the light crude oil, which would enhance the potential for small droplets of oil to become entrained in the water column, would also enhance the rate of hydrocarbon dissolution into water.

There would also be high potential for chronic effects of released crude oil on fish eggs and embryos (i.e., induction of deformities or mortality collectively termed blue sac disease). Many of the fish species present in the Mosquito Creek spawn in the spring and early summer. The eggs and embryos of these species could be exposed to total PAH concentrations in the river water that could be sufficiently high to induce deformities or cause mortality. In addition the potential for phototoxicity, caused by an interaction of UV light with PAHs accumulated in fish tissues, would be greatest for a crude oil release in summer due to high light intensity and long day length. Small fish that are lightly pigmented or transparent (i.e., embryos, larval and juvenile fish) are most susceptible to phototoxicity. In addition the potential for phototoxicity, caused by an interaction of UV light with PAHs accumulated in fish tissues, would be greatest for a crude oil release in summer due to high light intensity and long day length. Small fish that are lightly pigmented or transparent (i.e., embryos, larval and juvenile fish) are most susceptible to phototoxicity. The risk of phototoxicity could be partially mitigated by periods of high concentrations of suspended sediment and dissolved organic carbon present in the water.

Entrainment of small crude oil droplets in the water column also enhances the potential for light crude oils to interact with suspended sediment particles in the water column resulting in the formation of OPAs. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water, such as oxbows and backwaters. Formation of true OPAs is less likely to occur with heavy crude oils such as diluted bitumen, as the higher viscosity of the oil precludes the ready formation of fine droplets in the water column (Zhou et al. 2015). However, heavy oils can still contact sediment particles along the shoreline, and some accumulation of both light and heavy oils in depositional areas is likely, although the precise mechanisms of deposition may vary. Neither crude oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. During the high flow spring period, while neither oil is predicted to be on the water surface beyond 10.4 miles downstream of the release location within the first 24 hours of the release, it is possible that oil

accumulated in depositional areas could mobilize over time and move farther downstream towards, and potentially into the north end of Lower Rice Lake.

For a hypothetical release under spring freshet conditions, it is likely that most aquatic plants would still be dormant or submerged, and that environmental effects on this receptor type would be minimal. However, where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Submerged aquatic plants would be less vulnerable, as they would be exposed primarily to dissolved hydrocarbons, and are not considered likely to be among the more sensitive groups of aquatic biota to such exposure. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem could be oiled). However, flooded riparian areas and wetland habitats would also be exposed to the released oil, and if not properly remediated, crude oil residues could kill plants in these areas. This could affect the biological integrity and productivity of the habitat, and potentially lead to erosion and further damage to the habitat.

Wild rice is an emergent aquatic plant of biological and cultural importance and occurs where Mosquito Creek enters Lower Rice Lake. Wild rice provides a food source and nesting cover for many birds, and is also harvested as a food source by people in the area. Based on the 24 hour simulations, the longest modeled trajectory during the high flow period extended 10.4 miles downstream of the releases and 1.4 miles upstream of Lower Rice Lake. This suggests that it is unlikely that released crude oil during this season would result in adverse effects to wild rice in Lower Rice Lake. However, it is possible that oil accumulated in depositional areas could mobilize with time and move farther downstream towards, and into the north end of Lower Rice Lake. This would be similar to the process that led to accumulation of diluted bitumen in the upper end of Morrow Lake following the Marshall, Michigan oil spill in 2010. The mobilization of oil that accumulates in depositional areas would be more likely to occur for the heavy crude oil which weathers more slowly and is more persistent than the light crude oil. Accumulation of crude oil in the sediment at the north end of Lower Rice Lake could be detrimental to the germination and growth of wild rice.

Crude oil released during the summer-fall (average flow) period is predicted to travel downstream, stranding on grassy and marshy banks and losing volatile components of the oil to evaporation. Results for Bakken and Cold Lake crude oil types provide bounding cases for the products likely to be carried in the pipeline. Based on a 24 hour model run, the OILMAP Land simulations indicate that crude oil could be carried between 2.6 and 9.8 miles downstream from the point of release under summer-fall average-flow conditions. For heavy oil and light oil, stranding on creek banks would be the primary fate, with only small amounts of evaporative weathering of the heavy oil and moderate amounts of weathering for lighter oils within the first 24 hour period. The lower water flow in summer-fall could result in less dilution of water soluble components in the creek as compared to spring flow. However, the lower flow rates would be accompanied by lower turbulence in the water column, and a reduced tendency for crude oil to be dispersed as fine droplets in the water column. Periodic drying of the creek headwaters during summer and fall conditions would also limit crude oil transport should a release occur

during a dry summer, as well as limiting the interaction between oil and aquatic receptors. As a result, acute lethality caused by narcotic effects on fish and benthic invertebrates are less likely during the summer-fall season than in spring. The potential for blue sac disease to harm or kill developing fish eggs and embryos is also lower, due to the timing which avoids the reproductive period for most fish species. Taking into consideration the lower river flow and turbulence, deposition of crude oil residues to sediment in areas of still water is also less likely than during the spring period. These factors would also limit the potential for downstream movement of submerged crude oil into Lower Rice Lake, and subsequent interaction with aquatic plants and wetland areas.

Under low flow winter conditions, neither of the two bounding crude oil types is predicted to enter Mosquito Creek. As such, a crude oil release in winter would not be expected to seriously affect aquatic receptors.

7.2.6.3 Semi-Aquatic Wildlife Receptors

Habitat of the Mosquito Creek downstream of the hypothetical release location supports amphibians (e.g., salamander, mudpuppy), reptiles (e.g., turtles, snakes), semi-aquatic birds (e.g., ducks, geese) and semi-aquatic mammals (e.g., muskrat, otter). Habitat along Mosquito Creek varies in quality for semi-aquatic wildlife receptors. The creek is generally narrow, with grassy, marshy or boggy banks, and flows through a corridor dominated by bog/marsh, bounded by agricultural lands. Semi-aquatic wildlife receptors (e.g., amphibians, turtles, waterfowl, muskrat, and mink) will certainly be present throughout the length of Mosquito Creek. While individuals may be affected by exposure to released oil in the immediate area of the creek during the spring freshet and the summer-fall average-flow conditions, regional populations of these animals will be robustly supported by the extensive wetland and aquatic habitats in the area. Crude oil from a hypothetical release is not predicted to enter Mosquito Creek in winter, so effects on semi-aquatic wildlife would be minimal in that season. Details on predicted environmental effects for amphibians and reptiles, birds and mammals are provided below.

7.2.6.3.1 Amphibians and Reptiles

Crude oil released to the Mosquito Creek during the spring (high flow) or summer-fall (average flow) seasons is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas in the riparian floodplain. The distance travelled would depend upon river flow and oil type. Based on OILMAP Land simulations, light oils oil is predicted to travel father downstream than heavy oil. For heavy oil, stranding on shore would be the primary fate, with only small amounts of evaporative weathering of the oil occurring within the first 24 hour period. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation.

Within the oil-exposed habitats along the river that support amphibians (adults, juveniles, and eggs), oiling effects including mortality would be observed. Turtles appear to be relatively

tolerant of external crude oil exposure, and although these animals are likely to become oiled, mortality of turtles as a result of this exposure is less likely. Reptiles like lizards and snakes are primarily terrestrial species and are less intimately associated with aquatic environments. As a result, exposure of these animals to released crude oils would be limited. After the Kalamazoo River oil release in 2010 snakes did not appear to be highly exposed to released oil. A release of light crude oil during the spring would likely have a greater effect than in summer due to the greater predicted downstream transport distance and interaction with greater areas of riparian and wetland habitats than later in the year.

Under low flow winter conditions, neither of the two bounding crude oil types is predicted to enter Mosquito Creek. As such, exposure of amphibians and reptiles in winter would not be expected. In addition, amphibians and reptiles undergo a dormancy period when temperatures drop below approximately 41 to 45°F. Therefore, even if crude oil were to reach the creek, it is unlikely that amphibians and reptiles would be materially exposed to or affected by the released oil.

7.2.6.3.2 Birds

Aquatic and semi-aquatic birds are those that use rivers, lakes, wetlands, and riparian areas as components of their habitat, particularly for nesting and feeding. These birds belong to a variety of guilds including but not limited to waterfowl, divers, gulls and terns, raptors, shorebirds, waders, and some songbirds. They have a variety of dietary preferences, including piscivory, insectivory, omnivory and herbivory. If exposed to external oiling, the ability of birds to maintain body temperature may be compromised, leading to death as a result of hypothermia. Even if they survive their initial exposure to crude oil, the exposure may require an increase in metabolic rate to survive. In turn this may compromise other life functions such as reproduction or growth. Birds that survive external oiling may experience toxicological stresses as a result of ingesting crude oil residues while preening or attempting to clean and restore the normal properties and functions of feathers. Birds can also transfer potentially lethal quantities of crude oil residue from their feathers to the external surface of eggs, resulting in death of developing embryos.

Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species which leave their summer (and often breeding) habitat in the fall for wintering areas farther south where they can find open-water habitat. However, some birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available. Timely capture and rehabilitation of oiled birds may help to mitigate the environmental effects of a crude oil release. During the spring (high flow) season, many migratory birds would be returning to riverine and lacustrine habitats in Minnesota, or migrating through these areas on their way to breeding habitats farther north. With cold water temperatures prevailing, aquatic and semi-aquatic birds contacted by crude oil are likely to die as a result of hypothermia. Waterfowl and other semi-aquatic birds present in the affected river reach would be most affected. Animals upstream, farther downstream, or occupying other nearby habitats, would likely be less affected as it is assumed that emergency response

measures to prevent or reduce further possible downstream transport of oil would be in place within 24 hours of the release.

Environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude. With rising water temperatures, mortality of lightly oiled adult birds due to hypothermia becomes less likely than in the spring. However, in the early summer, environmental effects could include egg mortality due to transfer of oil from the feathers of lightly oiled adult birds in the nest. Chronic adverse effects on the health of birds that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while preening, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure and areas of the creek with suitable habitat, which could range from 2.6 to 9.8 miles downstream from the release point.

Under low flow winter conditions, neither of the two bounding crude oil types is predicted to enter Mosquito Creek, and most aquatic or semi-aquatic birds would have migrated away from the area for wintering habitat farther south. As such, exposure of birds to released crude oil in winter would be very limited.

7.2.6.3.3 Semi-aquatic Mammals

While the semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, this assessment focuses particularly upon species that have a primary association with the aquatic environment such as muskrat and beaver (herbivores), American mink (*carnivore-piscivore*), and river otter (*piscivore*). These species are at greater risk of exposure to an oil release in water than terrestrial mammals.

Effects to semi-aquatic mammals are typically described in terms of direct physical effects (e.g., hypothermia due to loss of insulation), direct toxicological effects (e.g., gastro-enteropathy caused by ingestion of crude oil residues while grooming oiled fur or ingesting food), and indirect effects caused by changes to habitat (e.g., land cover and food availability). The spatial extent along Mosquito Creek where effects may occur, and the magnitude of effects, is related to the oil type released, season and flow rate. Effects to semi-aquatic mammals relate more to the amount of time spent in the water (and consequent exposure to physical oiling) than to dietary preferences. Timely capture and rehabilitation of oiled mammals may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, with cold water temperatures prevailing, semi-aquatic mammals contacted by crude oil are likely to die as a result of hypothermia. Based on the OILMAP Land simulations, the leading edge of the releases could range from 3.5 to 10.4 miles in extent. Animals upstream, farther downstream where there is no exposure, or occupying other nearby habitats, would likely be unaffected. Therefore, although mortality of some semi-aquatic mammals could be expected, large-scale (i.e., regional) population level effects are unlikely.

Environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude than those associated with a release during a spring freshet. With rising water temperatures, mortality of lightly oiled semi-aquatic mammals due to hypothermia is expected to be less likely than in the spring. Chronic adverse effects on the health of semi-aquatic mammals that survive their initial exposure to crude oil also are possible as a result of ingesting crude oil residues while grooming, or while consuming food items.

In the winter months, muskrat and beaver are likely to reduce their activity levels, although American mink and river otter would remain active. Animals that became oiled in the winter would be likely to rapidly die as a result of hypothermia.

7.2.6.4 Human and Socio-Economic Receptors

Crude oils are complex mixtures of hydrocarbon compounds. Light crude oils typically contain more VOCs than heavier crude oils, although diluted bitumens may contain similar amounts of VOCs to light crude oils, depending upon the type and amount of diluent they contain. Air quality in the vicinity of a crude oil release, and along the downstream corridor, would be affected by the release of VOCs (such as benzene, which is often used as an indicator substance) primarily within the first 24 hours of an oil release. Under spring and summer-fall conditions, most of the released CLB or Bakken crude oil is predicted to reach Mosquito Creek, spreading on land and on the water. In contrast, under winter conditions virtually all of the released crude oil is predicted to be retained in snow or fill depressions on land. Low air temperatures, as well as the relatively thick layer and limited surface area of crude oil retained in the snow pack, are expected to minimize release of volatile components to the atmosphere in winter.

Typical human health effects associated with short-term (acute) inhalation of volatiles from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term or repeated skin contact with crude oil may result in dermatitis. The case studies (Section 7.1) do not reveal any instances of human fatality as a result of inhalation of crude oil vapor. Similarly, ATSDR (1995) report that there are no known instances of human fatality as a result of inhalation of vapor from fuel oils, which would be comparable to light crude oils.

The potential for VOC inhalation exposures by the public would be greatest near and downwind from the release site and near to Mosquito Creek while the released oil is on the water surface. For the most part, the areas around Mosquito Creek are sparsely populated (i.e., farms and country dwellings). The nearest HCA representing a populated area is located west of Lower Rice Lake, and not within the area identified to be potentially contacted by released oil within 24 hours of a release. One farm is located within approximately 300 ft of the overland flow path between the hypothetical point of release and the head of Mosquito Creek, and a number of other homes are located within a similar distance of Mosquito Creek, upstream of Lower Rice Lake. In the unlikely event of a crude oil release, a human fatality is highly unlikely. Most of the volatile hydrocarbons would be lost within the first 24 hours following a release of crude oil.

Residents in close proximity to the flow path would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. It is also expected that emergency response personnel would contact such residents and advise them to evacuate. Actual or potential exposure to crude oil vapor may result in residents leaving, or being advised to leave their homes for a period of time while the emergency response takes place.

No drinking water HCAs were identified along the path of the release. However, a number of homes are located along the trajectory of the overland flow path and adjacent to Mosquito Creek upstream of Lower Rice Lake. It is assumed that residents of these homes rely on groundwater as a drinking water source. In the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. Based upon case studies involving crude oil releases elsewhere, this process could take a few days to two weeks, but reports of crude oil releases affecting private wells are rare, making this an unlikely effect.

Relatively little has been published regarding the long-term effects of exposure to an oil release. Health effects observed in residents and clean-up workers in the months following an oil release generally do not persist over the long term (Eykelbosh 2014). The International Agency for Research on Cancer (IARC 1989) has determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans. Although toxicological effects from short-term exposure to volatile hydrocarbons are reversible when exposure is reduced, other health effects such as anxiety and depression may occur, and may persist, regardless of whether the individual was physically exposed to hydrocarbons.

Effects of a crude oil release on human receptors would be generally similar for the spring (high flow) and summer-fall (average flow) seasons, except that warmer temperatures and slower river flow velocities in the summer would promote more rapid evaporation of volatile hydrocarbons in a smaller area, whereas higher river flow velocity in the spring freshet period would transport the released oil farther downstream within the first 24 hours, potentially resulting in lesser exposures, but to a larger number of people. The distance of downstream oil transport depends upon river flow rate, oil type and bank type. Based on OILMAP Land simulations of lighter oils are predicted to travel father downstream than heavier oils (Figure 7-7 and Figure 7-8). As a result, a release of the light crude oil may affect a larger number of individuals than a release of the heavy crude oil type. Both Bakken crude oil and Cold Lake diluted bitumen are expected to contain similar overall amounts of volatile hydrocarbons, so differences related to the chemical characteristics of the released oil are likely to be minor.

Recreation, tourism, forestry and agriculture are the major land uses in the area of Mosquito Creek and Lower Rice Lake. Based on the 24 hour simulations and taking release response activities into account, neither heavy nor light crude oil is predicted to move on the water surface beyond 10.4 miles downstream of the releases. However, it is possible that oil accumulated in depositional areas would mobilize with time and move farther downstream,

towards and potentially into the north end of Lower Rice Lake. Such accumulation of crude oil could potentially affect the growth and harvesting of wild rice in this area. Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Recreational activities along the predicted downstream migration route would be disrupted following a release of crude oil. Under winter conditions the released crude oil would remain on land near the release location. Fisheries and public health officials typically close fisheries or issue guidance to avoid consuming fish until it is confirmed through monitoring that fish consumption is not a threat to public health. This standard approach is an effective mitigation strategy to protect human receptors for contact with chemical constituents of released crude oil.

7.2.6.5 Summary and Conclusions

Expected environmental effects to key ecological and human environment receptors after a hypothetical large crude oil release to Mosquito Creek, upstream of Lower Rice Lake, have been assessed. The proposed pipeline could carry a variety of crude oil types ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB), and the discussion of expected environmental effects on receptors considers these crude oil types as bounding conditions. Potential terrestrial receptors, aquatic receptors, semi-aquatic wildlife receptors and human and socio-economic receptors were screened to identify those most likely to have interactions with released crude oil. The results of this assessment are summarized in Table 7-50.

Table 7-50 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Mosquito Creek

Receptor	Expected Environmental Effects of Released Crude Oil to Mosquito Creek	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Terrestrial Receptors			
Soils	An assumption made in the fate modeling is that crude oil released under spring and summer-fall conditions would flow over 0.6 miles of land before reaching the headwater of Mosquito Creek, where the majority would be transported downstream. Under winter conditions released crude oil would remain on land. In the event of an actual oil release, any oil on land would undergo prompt and effective remediation. Residual effects on plant communities, soil or groundwater quality are unlikely.	SAME	SAME
Groundwater		SAME	SAME
Terrestrial Vegetation		SAME	SAME
Aquatic Receptors			
River (Mosquito Creek)	Both light and heavy oil would reach Mosquito Creek via overland flow under spring and summer-fall conditions, with subsequent physical transport downstream from the release location. Lighter crude oils are predicted to travel farther downstream than heavier crude oils, but would be thinner and less persistent on the water. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column, meaning potentially toxic fractions of the light oils would more readily dissolve into the water column. Under winter conditions the released crude oil would remain on land. Light oils have a larger bioavailable component to aquatic organisms.	MORE	LESS
Lake (Lower Rice Lake)	Neither heavy nor light crude oil is predicted to move on the water surface beyond 10.4 miles downstream of the releases (based on the 24 hour simulations, and taking release response activities into account). Therefore, direct effects of released crude oil on Lower Rice Lake are unlikely. However, it is possible that oil accumulated in and not recovered from depositional areas could mobilize over time and move farther downstream, into the north end of Lower Rice Lake. This phenomenon would be more likely for the more persistent diluted bitumen than for a lighter crude oil which would undergo more rapid weathering and biodegradation.	LESS	MORE

Table 7-50 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Mosquito Creek

Receptor	Expected Environmental Effects of Released Crude Oil to Mosquito Creek	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Sediment	Lighter crude oils are predicted to travel farther downstream than heavier crude oils under spring and summer-fall conditions. Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. The low viscosity of the lighter type crude oils could potentially result in a larger amount of oil entrainment as fine droplets as compared to heavier blends, resulting in the formation of OPAs, which could both sink, and enhance biodegradation. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water. The diluted bitumen crude oil type is less likely to be entrained into the water as fine droplets, and therefore true OPA formation is unlikely to occur. However, contact between the weathered diluted bitumen and shorelines is also likely to result in mixing of mineral particles into the crude oil, which could then be deposited to sediments as aggregates of oil and mineral in larger droplets or globules. If not recovered, these aggregates could move downstream with bedload until a stable depositional environment was reached, potentially in the north end of Lower Rice Lake.	LESS	MORE
Shoreline and Riparian Areas	Both light and heavy oil would travel downstream from the release location. Lighter crude oils are predicted to travel farther downstream than heavy crude oil under spring and summer-fall conditions, but would be thinner and less persistent where they contacted shorelines and riparian habitat. For heavy oil, thicker oiling of shorelines is predicted, with shorter overall transport distance. For light oil, stranding would also be the primary fate, but considerably more of the released oil would be lost to evaporation. Flooding of riparian and wetland habitats in spring could lead to stranding of crude oils in this habitat, with heavy crude oil likely to be deposited as patties or tar balls, which would be persistent. This is in contrast to light crude oil which would be deposited as a thin layer or sheen.	LESS	MORE
Aquatic Plants	Where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Submerged aquatic plants are less vulnerable. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem was oiled). Wild rice is an emergent aquatic plant of ecological and cultural importance, and occurs where Mosquito Creek enters Lower Rice Lake. Based on the 24 hour model simulations, neither heavy nor light floating crude oil is predicted to move on the water surface beyond 10.4 miles downstream of the hypothetical release point (which is approximately 1.4 miles upstream of Lower Rice Lake). The light oil is predicted to be more mobile, and would affect a larger area of habitat. However, it is also possible that heavy oil accumulated in depositional areas would mobilize with time and move farther downstream towards and into Lower Rice Lake, thus interacting with this resource.	SAME	SAME

Table 7-50 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Mosquito Creek

Receptor	Expected Environmental Effects of Released Crude Oil to Mosquito Creek	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Benthic Invertebrates	In the short-term, the low viscosity of light crude oil would result in greater potential for oil entrainment as fine droplets, as compared to heavier blends. This would enhance dissolution of low molecular weight aliphatic and aromatic hydrocarbons into water (potentially resulting in acute toxicity), in addition to promoting oil-particle interaction and potential deposition of oil to sediment. For heavy crude oil, there would be less potential for dissolution of hydrocarbons into the water, but greater long-term potential for deposition of tar balls and patties as a result of oil interaction with sediment. These could accumulate in depositional areas, resulting in chronic effects on benthic invertebrates.	MORE	LESS
Fish	Environmental effects on fish would be limited to areas affected by the released oil. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column. This would enhance the dissolution of potentially toxic fractions of the light oil into the water column. As a result, the potential for acute toxicity to fish due to narcosis would be greater for the light oil than for heavy oil. Potential chronic effects on fish eggs and embryos (i.e., blue sac disease) could also occur, but would be most likely to occur in spring and early summer, when most species spawn.	MORE	LESS
Semi-Aquatic Wildlife Receptors			
Amphibians and Reptiles	Light crude oil is predicted to travel farther downstream under spring and summer conditions than heavy crude oil, but would be thinner and less persistent on the water. Flooding of riparian habitat and marshes in spring could lead to stranding of crude oils in this habitat. Higher potential would exist for effects to amphibians than for adult turtles (e.g., external oiling and narcotic effects similar to fish and benthic invertebrates), which appear to be somewhat tolerant of external oiling.	MORE	LESS
Birds	Light crude oil is predicted to travel farther downstream under spring and summer conditions than heavy crude oil, so environmental effects could be more spatially extensive for light crude oil types than for heavy crude oil. Cold water in the spring, in combination with greater downstream movement of released oil, suggests that environmental effects of released oil could be greatest for a light crude oil in spring. In winter few if any aquatic or semi-aquatic birds would be present. Crude oil from a hypothetical release in that season is not predicted to enter Mosquito Creek, so effects on birds would be minimal.	MORE	LESS

Table 7-50 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Mosquito Creek

Receptor	Expected Environmental Effects of Released Crude Oil to Mosquito Creek	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Semi-aquatic Mammals	Light crude oil is predicted to travel farther downstream under spring and summer conditions than heavy crude oil, so environmental effects could be more spatially extensive for light crude oil types than for heavy crude oil. Cold water in the spring, in combination with greater downstream movement of released oil, suggests that environmental effects of released oil could be greatest for a light crude oil in spring. In winter crude oil from a hypothetical release is not predicted to enter Mosquito Creek, so effects on semi-aquatic mammals would be minimal in that season.	MORE	LESS
Human and Socio-Economic Receptors			
Air Quality	Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns. Light crude oils typically contain more VOCs than heavier crude oils, although the VOC content of diluted bitumen may be similar to that of light crude oil, depending on the type and quantity of diluent used in its manufacture. Air quality in the vicinity of the oil release would be most affected within the first 24 hours of an oil release. Light crude oil is likely to be transported farther downstream within 24 hours than heavy crude oil. As a result, environmental effects on air quality could be more spatially extensive for light crude oil. Under winter conditions, the cold temperatures and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS
Human Receptors	Typical human health effects associated with short-term inhalation of VOCs from crude oil releases include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain; fatality is unlikely. Residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most volatile hydrocarbons would be lost within 24 hours following a release. Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health. Under winter conditions, cold temperatures and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS
Public Use of Natural Resources	Emergency response workers, in cooperation with public health and safety officials, would be active in notifying the public about the release, and isolating, containing and recovering released crude oil. No drinking water HCAs were identified along the path of the release. However, a number of homes are located near the flow path. In the event of a crude oil release, residents would be notified and testing would be completed to confirm the safety of private drinking water supply wells. Recreational activities would be disrupted along the predicted downstream migration route following a release of crude oil.	SAME	SAME

LINE 3 REPLACEMENT PROJECT:
ASSESSMENT OF ACCIDENTAL RELEASES: TECHNICAL REPORT

Assessment of Environmental Effects of Oil Releases
January 13, 2017

7.3 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE MISSISSIPPI RIVER AT BALL CLUB

The proposed pipeline could potentially cross under the Mississippi River 1.25 miles west of Ball Club, Minnesota and 400 ft south of U.S. Highway 2. This scenario captures a hypothetical release of crude oil directly to the Mississippi River, with downstream transport from the hypothetical release point to the south and east. The river channel in this area is relatively well defined, with many oxbows, backwaters and sloughs. The river margins include extensive riparian wetlands in a wide floodplain.

The Mississippi River to the south and east of the hypothetical release location is joined by the Leech Lake River approximately 4.7 miles downstream. Below the Leech Lake River confluence, the Mississippi River deepens and the riparian marsh expands as flow moves towards White Oak Lake (MN DNR 2016e). Beyond White Oak Lake the Mississippi River flows south and then east towards Grand Rapids, Minnesota. As identified in Chapter 4, the Mississippi River near Ball Club is part of the Chippewa Plains, a subsection of the Northern Minnesota Drift and Lake Plains Section of the greater Laurentian Mixed Forest Province (MN NDR 2006).

7.3.1 Description of the Freshwater Environment

The Mississippi River near Ball Club, Minnesota flows through a forested area, but the river has a wide floodplain lined with extensive marsh and grass. The riparian marshes and numerous abandoned river segments (oxbows) downstream of the crossing are considered important but they are afforded no special protection as WMAs (MN DNR 2016e). The river channel near the hypothetical release point is about 70 ft wide. The average velocity of the Mississippi River changes with season, with slowest velocities (e.g., about 0.4 ft per second) expected during low flow periods in the winter, and greater velocities (e.g., about 1.5 ft per second) during the spring high flow period. As a result of the flow regime, sand bars are often present on the inside of river bends, and occasionally present in the river channel.

Under low and average flow conditions the main channel of the Mississippi River passes to the south of White Oak Lake, with only small marshy streams connecting them. Under high river flow conditions, more substantial hydraulic connections exist between the river and lake. White Oak Lake is 38 acres in size and approximately 16 ft deep and is bordered to the north by the communities of Zemple and Deer River. The MN DNR does not report any information about aquatic wildlife on White Oak Lake; however, in nearby Ball Club Lake, many fish species are present (e.g., northern pike, black crappie, smallmouth bass; MN DNR 2016f).

The oxbows along the Mississippi River downstream of the potential pipeline crossing location are expected to support spawning fish, mink, raccoon, otter, wood ducks, mallard, and merganser (MN DNR 2016e). Within the Chippewa Plains subsection, 83 species are considered SGCN; these include birds (60 species), fish (4 species), insects (8 species), mammals (6 species), mollusks (2 species), and reptiles (2 species) (MN DNR 2006). Of these, 22 are listed by the federal

government as endangered, threatened, or species of concern (MN DNR 2006; MN DNR 2016d). It is foreseeable that some of these SGCN would utilize aquatic habitats along the Mississippi River and White Oak Lake.

Several access points downstream from the proposed pipeline crossing location were visited in May, 2016, to provide additional insight into baseline environmental conditions for the Mississippi River downstream of Ball Club. Representative site photographs are provided in Figure 7-9 through Figure 7-12. Field observations are summarized in Table 7-51.

Figure 7-9 Mississippi River and Riparian Habitat Approximately 4.7 Miles Downstream of Pipeline Crossing Looking South (Confluence of Leech Lake River)

Figure 7-10 Mississippi River and Riparian Habitat Approximately 4.7 Miles Downstream of Pipeline Crossing Looking West (Upstream)

Figure 7-11 Mississippi River and Riparian Habitat Approximately 31 Miles Downstream of Pipeline Crossing

Figure 7-12 Mississippi River and Riparian Habitat Approximately 56 Miles Downstream of Pipeline Crossing

Table 7-51 Environmental Characteristics Observed at Selected Access Points on the Mississippi River Downstream of Pipeline Crossing Near Ball Club, MN in May 2016

Access Point	Latitude Longitude	Notes
Mississippi River #10 State Water Access Site (Boat Ramp) 4.7 miles downstream of pipeline crossing	47.3022 -93.9037	Habitat Description: At the confluence of the Mississippi and Leech Lake rivers. Broad floodplain with sedge wet/meadow, shrub swamp, and emergent marsh as the dominant plant community types. Some hardwood swamp and temporarily flooded aspen woods also present. The invasive plant Phragmites (reed grass) is common in the vicinity. Wildlife observed: yellow-bellied sapsucker, yellowthroat, green heron, tree swallow.
Mississippi River, #2 State Water Access Site (Boat Ramp) 31 miles downstream of pipeline crossing	47.6256 -93.7610	Habitat Description: River margin has good quality emergent marsh and wet/sedge meadow plant communities present. The invasive plants hybrid/narrowleaf cattail and Phragmites are common in some areas. Submergent vegetation is dominated by water celery. Floodplain forest is also present in the area. Adjacent upland areas include good quality forest dominated by aspen-birch. Wildlife observed: red-wing blackbird, yellowthroat

Table 7-51 Environmental Characteristics Observed at Selected Access Points on the Mississippi River Downstream of Pipeline Crossing Near Ball Club, MN in May 2016

Access Point	Latitude Longitude	Notes
Mississippi River at Herb Beers State Water Access Site 56 miles downstream of pipeline crossing	47.1288 -93.4051	Habitat Description: The floodplain in this area is dominated by a mix of floodplain forest and wet/sedge meadow. The invasive, nonnative reed canary grass occurs occasionally here. Floodplain transitions into terrace forest dominated by bur oak and green ash on Mississippi soils. Wildlife observed: Yellow throat, Baltimore oriole

7.3.2 High Consequence Area Assessment for the Mississippi River near Ball Club Crossing Location

As defined in Chapter 7.0, HCAs include populated areas, drinking water source areas, ecologically sensitive areas, and commercially navigable waterways. Sensitive AOIs include Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks).

The locations of the various HCAs and AOIs near the hypothetical release location and the predicted trajectory of the floating oil are illustrated in Figure 7-13. Table 7-52 and Table 7-53 provide brief descriptions of the HCAs and AOIs for the hypothetical crude oil release location.

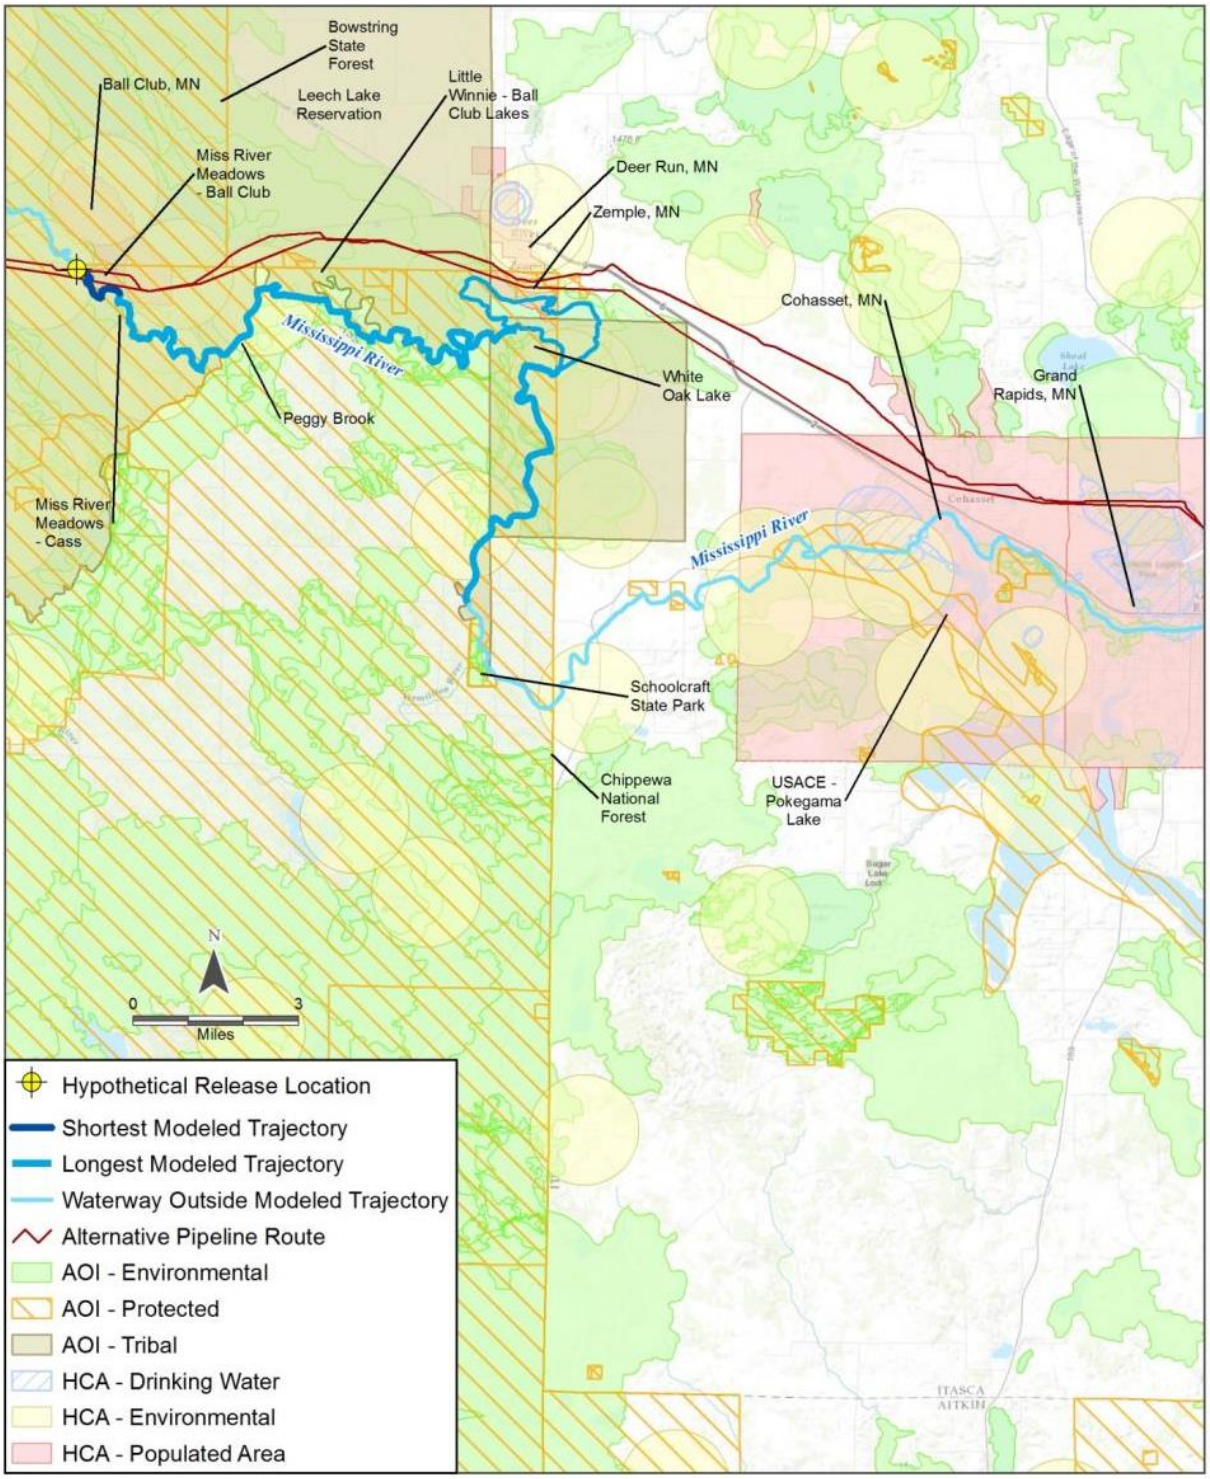

Figure 7-13 HCAs and AOIs Potentially Affected by a Crude Oil Release at the Mississippi River near Ball Club Crossing Location

Table 7-52 HCAs Potentially Affected by a Release of CLB and Bakken Crude Oil at the Mississippi River near Ball Club Crossing Location

HCA Type	HCA Subtype	Description / Locations
Environmentally Sensitive Area	N/A	N/A
Population Area	Other	Ball Club, MN Zemple, MN
NOTE: Data for the HCA analysis were obtained from the United States Department of Transportation: Pipeline and Hazardous Materials Safety Administration (USDOT PHMSA) HCA datasets plus additional HCAs compiled by Enbridge during 2010 and 2013.

7.3.3 Selection of Key Ecological and Human Environment Receptors for Mississippi River near Ball Club Crossing Location

Taking into account environmental characteristics of the Mississippi River near Ball Club, the potential interactions of released crude oil with key ecological and human environment receptors were screened to identify key receptors for the subsequent environmental effects analysis. The rationale and results of this screening step are provided in Table 7-54.

Table 7-54 Key Ecological and Human Environment Receptors for the Mississippi River Near Ball Club

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mississippi River near Ball Club Scenario	Selected (Y/N)
Terrestrial Receptors		
Soils	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with no holdup of oil on land. Any oil that reaches soil would be physically remediated to established standards.	N
Groundwater	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with no holdup of oil on land. In the event of an actual oil release, effects on groundwater quality would be localized and/or negligible.	N
Terrestrial Vegetation	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with no holdup of oil on land. Any oil that reaches soil would be physically remediated and vegetative cover would be restored as part of the cleanup process.	N
Aquatic Receptors		
Rivers (Mississippi River)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver.	Y
Lakes (White Oak Lake)	High. An assumption made in the fate modeling for this scenario is that oil released under spring conditions, could be transported downstream in the Mississippi River and enter White Oak Lake.	Y
Sediment	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver. This allows potential interaction and/or deposition of crude oil residues to sediments.	Y
Shoreline and Riparian Areas	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver. This allows potential interaction with shoreline and riparian habitat.	Y
Wetlands	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver and potential interaction with wetlands along the river and White Oak Lake.	Y
Aquatic Plants	High. Mississippi River and White Oak Lake support aquatic plant communities.	Y
Benthic Invertebrates	High. Mississippi River and White Oak Lake support benthic invertebrate communities.	Y
Fish	High. Mississippi River and White Oak Lake support fish communities.	Y
Semi-Aquatic Wildlife Receptors		
Amphibians and Reptiles	High. Mississippi River and White Oak Lake support semi-aquatic amphibians and reptiles.	Y

Table 7-54 Key Ecological and Human Environment Receptors for the Mississippi River Near Ball Club

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mississippi River near Ball Club Scenario	Selected (Y/N)
Birds	High. Mississippi River and White Oak Lake support waterfowl and other semi-aquatic birds.	Y
Semi-aquatic Mammals	High. Mississippi River and White Oak Lake support semi-aquatic mammals.	Y
Human and Socio-Economic Receptors		
Air Quality	High. The community of Ball Club, Minnesota is 1.25 miles west of the hypothetical release location. The communities of Deer River and Zemple, Minnesota are approximately 1 mile from White Oak Lake. Some homes are located along the downstream flow path for released crude oil. Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns.	Y
Human Receptors	High. The community of Ball Club, Minnesota is 1.25 miles west of the hypothetical release location. The communities of Deer River and Zemple, Minnesota are approximately 1 mile from White Oak Lake. Some homes are located along the downstream flow path for released crude oil. Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health.	Y
Public Use of Natural Resources	High. The Mississippi River near Ball Club, Minnesota and White Oak Lake area is shared by the Leech Lake Reservation and Bowstring State Forest. Effects on air and water quality, or the presence of crude oil residues in the sediment, riparian or wetland habitat, could potentially disrupt public use of natural resources (e.g., wild rice harvest, drinking water supplies, hunting, fishing, recreation).	Y

7.3.4 Modeled Conditions at the Release Location

A description of key modeling assumptions for the environmental effects analysis for the Mississippi River near Ball Club scenario is provided in this section. The OILMAP Land software was used by RPS ASA to simulate hypothetical releases of CLB and Bakken crude oils into the Mississippi River near Ball Club (Chapter 4.0) for a 24 hour period. A longer time period was not modeled as it was assumed that emergency response measures to prevent further downstream transport of released oil would be in place within the 24 hour period. While OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column (Chapter 5.0). No overland transport of released CLB or Bakken crude oil was modelled for this hypothetical release location, as it was assumed that released oil would directly enter the watercourse (Chapter 4.0). This is a worst-case assumption for a release of crude oil near the watercourse.

The two crude oil types provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (CLB/CLWB, heavy diluted bitumen crude oil types having higher viscosity and density). Seasonal variations in river flow velocity, temperature, wind speed, and snow and ice cover were all considered at the release location. A summary of key variables is provided in Table 7-55.

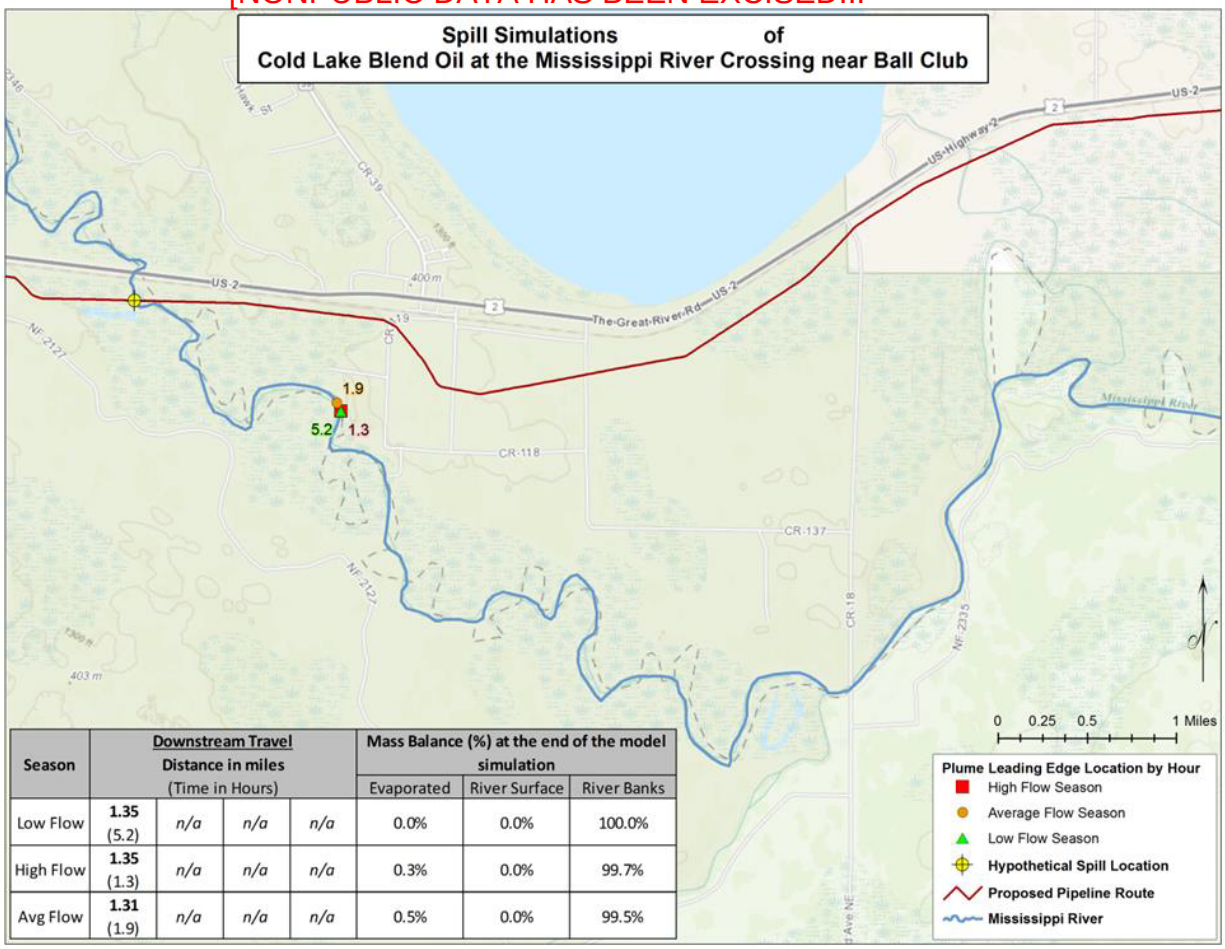
The shore type for the majority of the Mississippi River in the region of the hypothetical release is marsh. Marsh shore types have high potential to trap and retain crude oil. Because of the uncertainty around how much oil would be able to infiltrate the marshy shoreline under the seasonal flow conditions, the downstream trajectory of released oils was simulated also assuming a grass shoreline, for which oil retention capacity is lower. Both sets of results are presented here independently. It is anticipated that if an actual release were to occur, downstream oil transport would be somewhere between the two predicted downstream distances.

Table 7-55 Environmental and Hydrodynamic Conditions for the Three Modeled Periods at the Mississippi River at Ball Club Crossing

Season	Month	Air Temperature (°C)	Wind Speed (m/s)	Average River Velocity (m/s)
Low Flow (Winter)	March	-3.61	4.51	0.12
Average Flow (Summer-Fall)	August	18.92	3.51	0.31
High Flow (Spring)	April	5.00	4.88	0.47
NOTE: A velocity of 1 m/s is equivalent to 2.25 miles per hour.				

The highest average flow velocity of the Mississippi River at Ball Club coincides with the spring freshet (i.e., April–June), a result of rising temperatures and snowmelt. Average flow would typically occur in summer and fall seasons. August, the month with the warmest temperature, was selected to represent the maximum amount of evaporation. The lowest flow rate occurs in winter (i.e., January-March), and was typified by freezing conditions and probable ice cover on water.

The crude oil release volume was calculated as a full bore rupture, with a maximum time to response in the pipeline Control Center of 10 minutes, followed by a 3-minute period to allow for valve closure. The release volume therefore represents the volume of oil actively discharged in the period of time required to detect and respond to the event (taking into consideration the pipeline diameter, pipeline shutdown time, pipeline design flow velocity), followed by the volume of oil lost due to drain-down of the elevated segments of pipeline. The maximum 13-minute response time to valve closure is an Enbridge standard for safe operations and leak detection. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown, and full valve closure in the affected pipeline section. While



13 minutes is the maximum time for valve closure, this is a conservative assumption, since a response through to valve closure is expected to occur in less than 13 minutes in a full bore rupture leak scenario. Based on these assumptions, the site-specific hypothetical release volume was estimated of Bakken, CLB or CLWB crude oil.
[NONPUBLIC DATA HAS BEEN EXCISED]

7.3.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils

A summary of the predicted downstream trajectories and mass balance for Cold Lake and Bakken crude oils, under the three seasonal scenarios and for two shore types (i.e., marsh or grass), are provided in Figure 7-14 to Figure 7-17. These simulations are assumed to provide bounding conditions for a release of heavy or light crude oil types. The fate of most types of crude oil, if released, would lie within the envelope of predictions for the Cold Lake and Bakken crude oil types. The Cold Lake crude oil was assumed to be CLB for the high flow and average flow scenarios, and to be CLWB for the low flow (winter) scenario. As noted in Chapter 5, while OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column.

The maximum simulation duration using OILMAP Land was 24 hours, as it was assumed that emergency response measures to prevent or reduce further downstream transport of released oil would be in place within that length of time. Symbols on the drawings indicate the river seasonal flow condition (high corresponding to spring freshet, average corresponding to summer-fall conditions, and low corresponding to winter flow under ice). Numbers associated with the symbols indicate the predicted location of the leading edge of the released oil in the river after 6, 12, 18 or 24 hours. Numbers other than these (e.g., 5.2) indicate the time in hours of the predicted termination of downstream transport of the released oil due to adhesion or holdup of the oil along the river banks. Tables inserted within the Figures also provide information on the mass balance (i.e., oil remaining on the surface of the river, adhering to river banks, or evaporated to the atmosphere) of the released oil at relevant points in time after the start of the release.

Figure 7-17 Predicted Downstream Transport of Bakken crude at the Mississippi River at Ball Club Crossing Location Assuming Grassy Shore

7.3.5.1 Mississippi River at Ball Club Release During High Flow (Spring) Period

Under the high flow scenario and assuming a predominantly marshy shore, CLB was predicted to travel approximately 1.35 miles downstream in Mississippi River, with downstream transport being terminated 1.3 hours after the release (Figure 7-14). Almost all of the released crude oil (99.7%) was predicted to adhere to shorelines, with the balance evaporating. With the assumption of a grassy shore having less oil retention capacity, CLB was predicted to travel farther downstream (8.1 miles in 8 hours), with the majority also adhering to shorelines (Figure 7-15). It was assumed that emergency response measure to prevent further possible downstream transport of oil would be in place within 24 hours of the release.

Bakken crude oil was predicted to be transported approximately 6.4 miles downstream within 6.4 hours of a release assuming a predominantly marshy shore (Figure 7-14). At this time, approximately 29% of the Bakken crude oil was predicted to have evaporated to the atmosphere, with 71% adhering to shorelines. With the assumption of a grassy shore, Bakken crude oil was predicted to travel approximately 23 miles downstream over the 24-hour modeled period (Figure 7-15). Under these assumptions, the oil was predicted to reach and spread over the surface of White Oak Lake (1.47 square miles) to a thickness of 0.00004 inches. The Bakken crude oil was also predicted to continue to move downstream from White Oak Lake, another 6.9 miles. Approximately 39.8% of the Bakken crude oil was predicted to adhere to the shorelines of the Mississippi River and White Oak Lake, 0.2% was predicted to remain on the surface of White Oak Lake, 21.6% would remain on the river surface, and 38.4% was predicted to have evaporated into the atmosphere at the end of the 24 hour simulation. If left unmitigated, the Bakken crude oil remaining on the river surface after 24 hours could continue to move downstream, with weathering and oiling of shorelines continuing until all of the oil was removed from the water surface.

The release of Bakken crude oil under high flow conditions was predicted to result in oiling approximately farther downstream in Mississippi River than the CLB. The difference in the extent of downstream transport was primarily the result of the difference in shoreline retention. Because of its higher viscosity and adhesiveness, larger amounts of CLB are predicted to strand, as a thicker layer of oil on a given length of shoreline, than for the Bakken oil. Conversely, the same amount of Bakken crude oil would affect a greater length of shoreline, with a lesser thickness of oil. This result is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point was oiled to its maximum holding capacity for that oil type) as oil made its way downstream. In the event of an actual release, the downstream extents of CLB and Bakken crude oil may be more similar, and the effects of CLB may extend farther downstream than presented, with patchy coverage or partial oiling of shorelines.

A larger portion of Bakken crude oil was predicted to evaporate to the atmosphere than was predicted for CLB. This was due in part to the lighter and more volatile character of the Bakken crude oil. In addition, the greater downstream transport of the Bakken crude oil took more time, and resulted in more water surface area with oil, both of which would allow more of the released oil to evaporate. Volatile components of the CLB would continue to evaporate after becoming stranded on shoreline, but this process was not included within the OILMAP Land model for stranded oil.

7.3.5.2 Mississippi River at Ball Club Release During Average Flow (Summer-Fall) Period

Under average river flow conditions, and assuming a predominantly marshy shore, CLB crude oil was predicted to travel up to 1.31 miles downstream within 1.9 hours of the release at which time the downstream transport was predicted to terminate (Figure 7-14). At that time, approximately 0.5% of the released crude oil was predicted to have evaporated to the atmosphere, with the remaining 99.5% predicted to be adhering to shoreline. With the assumption of a grassy shore,

CLB was predicted to travel farther downstream (8.0 miles in 12 hours) with the majority of the release also adhering to banks (Figure 7-38).

Slightly more of the CLB crude oil was predicted to evaporate under the average river flow condition than under the high river flow condition (Figure 7-14 and Figure 7-15). This difference is due largely to the warmer temperatures in the summer-fall season as compared to the spring freshet, as well as the greater length of time and greater surface area of water that was predicted to be oiled before the end of the simulation.

Under average river flow conditions, Bakken crude oil was predicted to travel approximately 5.7 miles downstream within 8.8 hours of release, assuming a predominantly marshy shore (Figure 7-14). At this time approximately 35.1% was predicted to have evaporated to the atmosphere, with the remaining 64.9% predicted to be retained on shorelines. Under average river flow conditions, the Bakken crude oil was transported downstream at a slower velocity than under high river flow conditions, allowing more time for evaporation from the stream surface. With the assumption of a grassy shore with less oil retention capacity, Bakken crude oil was predicted to travel approximately 15.9 miles downstream over the 24-hour modeled period (Figure 7-15). The Bakken crude oil was predicted to be transported down the Mississippi River, past but not entering White Oak Lake due to low water levels, and to terminate just west of Little White Oak Lake. Approximately 30% of the Bakken crude oil was predicted to oil shorelines of the Mississippi River, 43.4% to evaporate into the atmosphere, and 26.6% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude on the river surface after 24 hours would be expected to continue downstream, with weathering and oiling of shorelines continuing until all the oil was removed from the water surface.

When compared to CLB under average river flow conditions, the Bakken crude oil was predicted to be transported farther downstream due to the lower shoreline oil retention values for the low viscosity Bakken crude oil, when compared to the more viscous and adhesive CLB. Although not modeled here, it is expected that a medium crude oil would exhibit fate and transport properties intermediate between those of the Bakken and CLB crude oil types.

7.3.5.3 Mississippi River at Ball Club Release During Low Flow (Winter) Period

Under low winter flow conditions it was assumed that Mississippi River would be frozen (100% ice coverage). It was also assumed that oil would be released directly into the river from the pipeline, which is located under the riverbed. Oil released into the water would remain in the water or be trapped under the ice. The ice cover would strongly limit or prevent evaporation to the atmosphere. Flow rates for the Mississippi River during these winter conditions result in minimum river velocities during March.

Under low river flow and assuming a predominantly marshy shore, CLWB was predicted to travel approximately 1.35 miles downstream in approximately 5.2 hours (Figure 7-14). After this time, all of the CLWB was predicted to be trapped along the river margins between the ice and the river bottom, or in hollows under the ice. With the assumption of a grassy shore with less oil retention

capacity, CLB was predicted to travel farther downstream (6.5 miles over the full 24-hour modeled period). Approximately 76% of the CLWB was predicted to be trapped along the river margins between the ice and the river bottom, or in hollows under the ice, and the remaining 24% was predicted to remain potentially mobile in the river below the ice. If left unmitigated, it is expected that the remaining CLWB would continue to move downstream until all of the oil was removed from the water.

Under low flow conditions, regardless of whether the shoreline was marshy or grassy, the Bakken crude oil was predicted to be transported approximately 6.5 miles downstream over the 24-hour modeled period. With a predominantly marshy shore, approximately 73% of the Bakken crude oil was predicted to be trapped along the river margins between the ice and the river bottom, or in hollows under the ice, with 27% remaining potentially mobile in the river below the ice at the end of the 24 hour simulation. With a grassy shore, approximately 12.2% was predicted to be trapped along the river margins between the ice and the river bottom, or in hollows under the ice, and the remaining 87.8% was predicted to remain potentially mobile in the river at the end of the 24 hour simulation. If left unmitigated, it is expected that the remaining Bakken crude in the river after 24 hours would continue to move downstream until all the oil was removed from the water.

Under winter conditions, the oil was predicted to move more slowly and to travel a shorter distance then than the average and high river flow conditions. Because the Bakken crude was released below the ice of the river, no oil was predicted to evaporate to the atmosphere.

7.3.6 Qualitative EHHRA for the Mississippi River near Ball Club

In this section the likely environmental effects of a crude oil release at the pipeline crossing location on the Mississippi River are described. A worst case crude oil release from a main-line pipeline, such as described here, would be an unlikely event (Chapter 4.0). The proposed pipeline could carry a variety of crude oil types, ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB). Therefore, the following discussion is based on the likely environmental effects of a crude oil release on relevant ecological and human environment receptors (identified in Section 7.3.3), using the predicted geographic extent of effects of released Bakken or CLB crude oil types over the 24 hour simulations as bounding conditions. Effects of season (including temperature, river flow conditions, and receptor presence/absence and sensitivity) were also considered in the analysis. The rationale supporting the effects analysis, based on case studies describing the effects of crude oil releases on the various ecological and human environment receptors, was provided in Section 7.1 and Table 7-54.

7.3.6.1 Terrestrial Receptors

For this modeling scenario, the hypothetical release of crude oil is assumed to enter into the Mississippi River with no overland flow. Environmental effects on soils, terrestrial vegetation and groundwater quality are assumed to be localized, limited in spatial extent, and readily

remediated using conventional clean-up techniques. The environmental effects of a crude oil release on land cover receptors are not considered further for this release scenario.

7.3.6.2 Aquatic Receptors

The aquatic environmental and ecological receptors that are most closely associated with the Mississippi River at Ball Club scenario are addressed in this section. These receptors include water and sediment quality in rivers and lakes, shoreline and riparian habitat, wetlands, aquatic plants, benthic invertebrates, and fish.

Crude oil released accidentally into the Mississippi River during the spring (high flow) or summer-fall (average flow) seasons would be predicted to travel downstream, interacting with vegetation and seasonal shoreline areas. The distance travelled would depend upon river flow, oil type and shoreline type. Based on OILMAP Land simulations, light oils oil is predicted to travel father downstream than heavy oil. Marshy shorelines are predicted to strongly limit the scope of downstream movement of crude oil, due to their high capacity to trap and retain released oil when compared to grassy shorelines (Figure 7-14 and Figure 7-15). Under high flow conditions and assuming a grassy shore (low retention), it was predicted that the Bakken crude oil could reach White Oak Lake and spread over its surface as a thin slick (0.00004 inches). For heavy oil, stranding on shore (whether marshy or grassy) would be the primary fate.

The effects of a crude oil release on benthic invertebrates and fish would depend on the characteristics of the released oil, and environmental conditions at the time of the release. Acute toxicity to fish is commonly but not always observed in association with crude oil releases, and is an indicator that, at least briefly, concentrations of dissolved hydrocarbons (particularly mono-aromatic hydrocarbons, some low molecular weight PAHs, and short-chain aliphatic hydrocarbons) are sufficiently high to cause acute toxicity due to narcosis. Light oils have low viscosity relative to heavier oils. Turbulence in the river water could potentially disperse light oil as small droplets in the water column, increasing the potential for toxic fractions of the light oil to dissolve into the water column. During the spring freshet, flow in the Mississippi River at Ball Club is likely to be sufficiently rapid and turbulent for such droplet formation to occur for the light crude oil, although heavy crude oil is less likely to be affected. As a result, the potential for acute toxicity to fish and benthic invertebrates could be greater for the light oil than for heavier oils.

During the spring high flow condition, the water level in the Mississippi River rises so that some of the oil transported down the river could spread over the surface of White Oak Lake. Approximately 0.2% of Bakken crude oil is predicted to be on White Oak Lake 24 hours after the release, as a very thin layer (0.00004 inches). The CLB crude oil is not predicted to reach White Oak Lake under any scenario. The large surface area of the lake would promote the rapid evaporation of volatile (and potentially water soluble) hydrocarbon constituents from the Bakken crude oil. Rapid evaporation could limit potential toxicity to fish within the lake. However, wind speeds are also potentially high during spring, so wave action on White Oak Lake could create turbulent conditions that would disperse light oil as small droplets in the water column. In

the unlikely event of a crude oil spill at Ball Club, Minnesota, narcotic effects of Bakken crude oil on fish and benthic invertebrates would be likely to occur in the Mississippi River upstream and downstream of White Oak Lake during the spring and summer-fall season. Narcosis could also occur in White Oak Lake in the spring, if water levels and flow conditions allowed the released Bakken crude oil to enter the lake.

There would also be high potential for chronic effects of released crude oil on fish eggs and embryos (i.e., induction of deformities or mortality collectively termed blue sac disease). Many of the fish species present in the Mississippi River spawn in the spring and early summer. The eggs and embryos of these species could be exposed to total PAH concentrations in the river and lake water that could be sufficiently high to induce deformities or cause mortality. In addition the potential for phototoxicity, caused by an interaction of UV light with PAHs accumulated in fish tissues, would be greatest for a crude oil release in summer due to high light intensity and long day length. Small fish that are lightly pigmented or transparent (i.e., embryos, larval and juvenile fish) are most susceptible to phototoxicity. The risk of phototoxicity could be mitigated by high concentrations of dissolved oxygen content (DOC) present in the water of the Mississippi River and White Oak Lake, which would absorb and limit the penetration of UV light into the water column.

Entrainment of small crude oil droplets in the water column during the spring freshet also enhances the potential for light crude oils to interact with suspended sediment particles in the water column resulting in the formation of OPAs. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water such as sediments near the many oxbows and twists in the Mississippi, as well as slowly moving areas and backwaters in the habitats where the Mississippi connects with White Oak Lake, and in addition, White Oak Lake could provide a depositional environment where crude oil might eventually accumulate, regardless of the season when an accidental release occurred. Formation of true OPAs is less likely to occur with heavy crude oils such as diluted bitumen, as the higher viscosity of the oil precludes the ready formation of fine droplets in the water column (Zhou et al. 2015). However, heavy oils can still contact sediment particles along the shoreline, and some accumulation of both light and heavy oils in depositional areas is likely, although the precise mechanisms of deposition may vary. Neither crude oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release.

The Mississippi River and White Oak Lake support emergent, floating and submerged aquatic plants. Where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Submerged aquatic plants would be less vulnerable, as they would be exposed primarily to dissolved hydrocarbons, and are not considered likely to be among the most sensitive groups of aquatic biota to such exposure. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem could be oiled). Wild rice is an emergent aquatic plant of biological and cultural importance in Minnesota, and is found in White Oak Lake. Wild rice provides a food source and nesting cover for many birds, and is also harvested as a food source by people in the area. For a hypothetical release under spring

freshet conditions, it is likely that most aquatic plants would still be dormant or submerged, and that environmental effects on this receptor type would be minimal. However, flooded riparian areas and wetland habitats would also be exposed to the released oil, and if not properly remediated, crude oil residues could kill plants in these areas. This could affect the biological integrity and productivity of the habitat, and potentially lead to erosion and further damage to the habitat. In the early summer, oiling of emerging wild rice plants could lead to growth inhibition or death. Later in the summer, oiling at water level of the stems of emerged plants (deposited during spring is unlikely to affect the plants. A release of crude oil in winter would have little direct effect on aquatic plants, as they would be in a dormant state.

Crude oil released during the winter (low flow) period could potentially pool on the frozen river surface. If the release was to occur directly to the river below the ice (as is assumed in the OILMAP Land model), or if there were openings in the ice that the released oil could penetrate, the oil could travel downstream under the ice, accumulating in the narrow gap between the ice and the river sediment, or accumulating in hollows under the ice as it moved. Results provided in Section 7.2.5.3 provide bounding cases for the products likely to be carried in the pipeline. The OILMAP Land simulations indicate that crude oil could be carried 1.35 to 6.5 miles downstream from the point of release under winter low-flow conditions. For both oil types, the winter ice would effectively inhibit evaporation, while providing greater potential for dissolution into the water column during the period of lowest dilution flow. Therefore, a release in winter could cause fish mortality due to narcosis. This result would be more likely for the light crude oil, which would spread out over a larger area, facilitating release of more water soluble constituents. The heavy crude oil would tend to remain in thicker localized accumulations, and rapid release of more water soluble constituents from a thick layer of crude oil is unlikely. Fish eggs and larvae would generally not be present during the winter, so effects on these life stages due to blue sac disease are not likely, although crude oil residues in water and sediment could, if not adequately remediated, affect fish eggs and larvae in the following spawning season. Phototoxicity is not likely to occur following a release of crude oil in winter due to short day length and lower light intensity in winter, reflection and absorbance of light by snow and ice cover on the lake, and absorbance of UV light by DOC in the water beneath the ice.

Both crude oil types could be accumulated in sediment after a release in winter, and both crude oil types would be subject to re-mobilization with spring breakup of the ice, and increasing water flow rates.

7.3.6.3 Semi-Aquatic Wildlife Receptors

Habitat along the Mississippi River downstream of the hypothetical release location supports amphibians (e.g., frogs, salamander), reptiles (e.g., turtles, snakes), birds (e.g., ducks, geese, shorebirds, raptors), and semi-aquatic mammals (e.g., muskrat, beaver, mink and otter). Details on predicted environmental effects for amphibians and reptiles, birds and mammals are provided below.

7.3.6.3.1 Amphibians and Reptiles

Crude oil released to the Mississippi River during the spring (high flow) and summer-fall (average flow) seasons is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas. The distance travelled would depend on the oil and shoreline type. The OILMAP Land simulations indicate that light oil will travel father downstream than heavy oil, with both types being retained more strongly by marshy shores, as compared to grassy shores (Figure 7-14 and Figure 7-15). Under spring (high flow) conditions and assuming a grassy shore, it was predicted that the Bakken crude oil could reach White Oak Lake and spread over its surface as a thin slick (0.00004 inches). For heavy oil, stranding on shore would be the primary fate.

Within the oil-exposed habitats along the river and lake that support amphibians (adults, juveniles, and eggs), oiling effects including mortality would be observed. Turtles appear to be relatively tolerant of external crude oil exposure, and although these animals are likely to become oiled, mortality of turtles as a result of this exposure is less likely. Reptiles like lizards and snakes are primarily terrestrial species and are less intimately associated with aquatic environments. As a result, exposure of these animals to released crude oils would be limited. After the Kalamazoo River oil spill in 2010 snakes did not appear to be highly exposed to spilled oil. A release of light crude oil during the spring would likely have a greater effect than in summer due to the greater predicted downstream transport distance and interaction with greater areas of riparian and wetland habitats than later in the year.

Amphibians and reptiles undergo a winter dormancy period when temperatures drop below approximately 41 to 45°F. At this time, amphibians and turtles typically bury themselves in river bottom substrates or other similar habitats. Therefore, during the winter (and likely up until April or May when winter ice is gone), these organisms would have very little exposure to released oil moving on the water surface or within the water column.

7.3.6.3.2 Birds

Aquatic and semi-aquatic birds are those that use rivers, lakes, wetlands, and riparian areas as components of their habitats, particularly for nesting and feeding. These birds belong to a variety of guilds including but not limited to waterfowl, divers, gulls and terns, raptors, shorebirds, waders, and some songbirds. They have a variety of dietary preferences, including piscivory, insectivory, omnivory and herbivory. If exposed to external oiling, the ability of birds to maintain body temperature may be compromised, leading to death as a result of hypothermia. Even if they survive their initial exposure to crude oil, the exposure may require an increase in metabolic rate to survive. In turn this may compromise other life functions such as reproduction or growth. Birds that survive external oiling may experience toxicological stresses as a result of ingesting crude oil residues while preening or attempting to clean and restore the normal properties and functions of feathers. Birds can also transfer potentially lethal quantities of crude oil residue from their feathers to the external surface of eggs, resulting in death of developing embryos.

Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species that leave their summer (and often breeding) habitat in the fall for wintering areas farther south where they can find open-water habitat. However, some birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available. Timely capture and rehabilitation of oiled birds may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, many migratory birds would be returning to riverine and lacustrine habitats in Minnesota, or migrating through these areas on their way to breeding habitats farther north. With cold water temperatures prevailing, aquatic and semi-aquatic birds contacted by crude oil are likely to die as a result of hypothermia. Waterfowl and other semi-aquatic birds present in the affected river and lake reach would be most affected. Animals upstream, farther downstream, or occupying other nearby habitats, would likely be less affected as it is assumed that emergency response measures to prevent or reduce further possible downstream transport of oil would be in place within 24 hours of the release.

In addition to the habitat offered by the Mississippi Rivers and its riparian habitats, White Oak Lake represent ideal habitat for a variety of aquatic and semi-aquatic bird species, including both breeding and migratory individuals. Therefore, potential for mortality of a large number (i.e., several hundred) of aquatic and semi-aquatic birds would exist, depending upon the precise circumstances and timing (e.g., spring and fall migration periods) of an accidental crude oil release. However, owing to the tremendous regional habitat resources for these birds, large-scale population-level effects are unlikely.

The environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude. With rising water temperatures, mortality of lightly oiled adult birds due to hypothermia becomes less likely than in the spring, and the temporary presence of large numbers of migrating individuals is unlikely. However, in the early summer, environmental effects could include egg mortality due to transfer of oil from the feathers of lightly oiled adult birds in the nest, or mortality of young birds due to direct oil exposure or the loss of a parent bird. Chronic adverse effects on the health of birds that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while preening, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure. Potential effects on aquatic and semi-aquatic birds in the fall would be similar to those in spring, although a smaller overall length of river habitat would be affected due to lower river flows. White Oak Lake is not predicted to be materially affected by a crude oil release under summer-fall conditions, and therefore substantial mortality of waterfowl and other semi-aquatic bird species in White Oak Lake is not an expected outcome in these seasons.

Under winter conditions (March), it was assumed that the Mississippi River would be frozen (100% ice cover). In addition, most waterfowl and other semi-aquatic bird species would migrate south in the winter. Therefore, a crude oil release in winter would be expected to have very limited effects on birds.

7.3.6.3.3 Semi-aquatic Mammals

While the semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, this assessment focuses particularly upon species that have a primary association with the aquatic environment such as muskrat and beaver (herbivores), American mink (*carnivore-piscivore*), and river otter (*piscivore*). These species are at greater risk of exposure to an oil release in water than terrestrial mammals.

Effects to semi-aquatic mammals are typically described in terms of direct physical effects (e.g., hypothermia due to loss of insulation), direct toxicological effects (e.g., gastro-enteropathy caused by ingestion of crude oil residues while grooming oiled fur or ingesting food), and indirect effects caused by changes to habitat (e.g., land cover and food availability). The spatial extent along the Mississippi River where effects may occur, and the magnitude of effects, is related to the season and river flow rate, and the type of oil released. Effects to semi-aquatic mammals relate more to the amount of time spent in the water and oil-contaminated riparian habitat (and consequent exposure to physical oiling) than to dietary preferences. Timely capture and rehabilitation of oiled mammals may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, with cold water temperatures prevailing, semi-aquatic mammals contacted by crude oil are likely to die as a result of hypothermia. Based on the OILMAP Land simulations, the potentially affected river reach could range from 1.3 to 23 miles in extent, and could include White Oak Lake during the spring, when it is directly connected to the Mississippi River. Animals upstream, farther downstream where there is no exposure, or occupying other nearby habitats, would likely be unaffected. Therefore, although mortality of a considerable number of semi-aquatic mammals could be expected, large-scale (i.e., regional) population level effects are unlikely. Environmental effects of a crude oil release in the summer-fall period are likely to be of a magnitude similar to or lesser than those associated with a release during spring. With rising water temperatures, mortality of lightly oiled semi-aquatic mammals due to hypothermia is less likely than in the spring. Chronic adverse effects on the health of semi-aquatic mammals that survive their initial exposure to crude oil are possible as a result of ingesting crude oil residues while grooming, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure.

In the winter months, muskrat and beaver are likely to reduce their activity levels, although American mink and river otter would remain active. Animals that became oiled in the winter would be likely to rapidly die as a result of hypothermia.

7.3.6.4 Human and Socio-Economic Receptors

Crude oils are complex mixtures of hydrocarbon compounds. Light crude oils typically contain more VOCs than heavier crude oils, although diluted bitumen may contain similar amounts of VOCs to light crude oils, depending upon the type and amount of diluent they contain. Air quality in the vicinity of a crude oil release, and along the downstream corridor, would be

affected by the release of VOCs (such as benzene, which is often used as an indicator substance) primarily within the first 24 hours of an oil release. For the Mississippi River at Ball Club hypothetical release location, human receptors would likely be present and in proximity to the river in the community of Ball Club. Scattered farms and country homes are located at intervals along the downstream flow path, although much of the area is quite isolated. The communities of Zemple and Deer River are located north of White Oak Lake, and could potentially be exposed to hydrocarbon vapors under certain circumstances, and were identified through the HCA analysis as "other population areas".

Under the spring, high flow condition, the Mississippi River flow is expected to spread into White Oak Lake due to high water levels. Released Bakken crude oil could move out from the main river channel and into this lacustrine habitat. This behavior is identified as a possibility for the Bakken crude oil, but not for the CLB, as the more viscous oil is predicted to be more strongly retained along shorelines closer to the release point. The spreading of the released oil onto the surface of White Oak Lake would provide a large surface area, which would promote the rapid evaporation of volatile hydrocarbon constituents from the light crude oil, with potential effects on human receptors located nearby in Zemple, Minnesota. Released crude oil is not predicted to enter White Oak Lake in the summer-fall seasons, and therefore air quality effects at Zemple would be minimal. In winter, the released crude oil is predicted to remain in the upper section of the river reach, and to be confined beneath ice in the river, so effects on air quality in winter would be negligible.

Typical human health effects associated with short-term (acute) inhalation of volatiles from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term or repeated skin contact with crude oil may result in dermatitis. The case studies (Section 7.1) do not reveal any instances of human fatality as a result of inhalation of crude oil vapor. Similarly, ATSDR (1995) report that there are no known instances of human fatality as a result of inhalation of vapor from fuel oils, which would be comparable to light crude oils.

The potential for VOC inhalation exposures to the public would be greatest near and downwind from the release site and near White Oak Lake, while the released oil is on the water surface. In the unlikely event of a crude oil release, residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most of the volatile hydrocarbons would be lost within the first 24 hours following a release of crude oil. It is also expected that emergency response personnel would contact such residents and advise them to evacuate. Actual or potential exposure to crude oil vapor may result in residents leaving, or being advised to leave their homes for a period of time while the emergency response takes place.

No drinking water HCAs were identified along the path of the release. However, in the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. Based upon case studies involving crude oil releases elsewhere, this

process could take a few days to two weeks, but reports of crude oil releases affecting private wells are rare, making this an unlikely effect.

Relatively little has been published regarding the long-term effects of human exposure to a crude oil release. Health effects observed in residents and clean-up workers in the months following such releases generally do not persist over the long term (Eykelbosh 2014). The International Agency for Research on Cancer (IARC 1989) has determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans. Although toxicological effects from short-term exposure to volatile hydrocarbons are reversible when exposure is reduced, other health effects such as anxiety and depression may occur, and may persist, regardless of whether the individual was physically exposed to hydrocarbons.

Effects of a crude oil release on human receptors would be generally similar for the spring (high flow) and summer-fall (average flow) seasons. In summer, the warmer temperatures and slower river flow velocities in the summer would promote more rapid evaporation of volatile hydrocarbons in a smaller area. The distance of flow depends upon oil type and bank type: based on OILMAP Land simulations (for a 24 hour model run) lighter oils oil are predicted to travel father downstream than heavier oils, with the downstream transport distance being a function of shoreline type and oil retention capacity (Figure 7-14 and Figure 7-15). Under spring (high flow) conditions and assuming a grassy shore, Bakken crude oil was predicted to reach White Oak Lake and to spread over its surface. As a result, a release of the light crude oil could affect a larger number of individuals than a release of the heavy crude oil type.

No overland transport of released crude oil was modelled for this hypothetical release location. Infiltration of crude oil into soil and subsequently into groundwater is assumed to be negligible.

The Mississippi River near Ball Club and White Oak Lake area is shared by the Leech Lake Reservation and Bowstring State Forest. Effects on air and water quality, or the presence of crude oil residues in the sediment, riparian or wetland habitat, could potentially disrupt public use of natural resources (e.g., wild rice harvest, drinking water supplies, hunting, fishing, recreation). Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. Fisheries regulators and public health officials typically close fisheries until it is confirmed through monitoring that fish consumption is not a threat to public health. This standard approach is an effective mitigation strategy to protect human receptors for contact with constituents in the oil.

7.3.6.5 Summary and Conclusions

Expected environmental effects to key ecological and human environment receptors after a hypothetical large crude oil release to the Mississippi River near Ball Club, Minnesota have been assessed. The proposed pipeline could carry a variety of crude oil types (ranging from very light

[e.g., Bakken crude oil] to heavy [e.g., diluted bitumen such as CLB], and the discussion of expected environmental effects on receptors is based on these crude oil types as bounding conditions. Potential terrestrial receptors, aquatic receptors, semi-aquatic wildlife receptors and human and socio-economic receptors were screened to identify those with the most likely interactions with released oil. The results of this assessment are summarized in Table 7-56.

Table 7-56 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Ball Club

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Ball Club	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Terrestrial Receptors			
Soils	It is assumed in the model that crude oil would enter directly into the Mississippi River with no holdup of oil on land. In the event of an actual oil release, any oil on land would undergo prompt and effective remediation. Residual effects on plant communities, soil or groundwater quality are unlikely.	SAME	SAME
Groundwater		SAME	SAME
Terrestrial Vegetation		SAME	SAME
Aquatic Receptors			
Rivers (Mississippi River)	Both light and heavy oil would travel downstream from the release location, affecting the Mississippi River. Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, but would be thinner on the water, and less persistent where they contact shoreline habitat. Both light and heavy crude oils are predicted to travel similar travel distances under winter conditions, although more of the heavy oil would be likely to remain trapped along the edges of the rivers. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column, meaning that potentially toxic fractions of the light oils would more readily dissolve into the water column.	MORE	LESS
Lakes (White Oak Lake)	While light and heavy oil would both travel downstream from the release location in all three flow conditions, only light oil (e.g., Bakken crude oil) was identified as having the potential to enter White Oak Lake, under spring high flow conditions.	MORE	LESS

Table 7-56 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Ball Club

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Ball Club	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Sediment	Lighter crude oils are predicted to travel farther downstream than heavier crude oils in spring and summer-fall conditions, with both oil types travelling similar distances under winter conditions. Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. The low viscosity of the lighter type crude oils could potentially result in a larger amount of oil entrainment as fine droplets as compared to heavier blends, resulting in the formation of OPAs, which could both sink, and enhance biodegradation. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water such as sediments near the many oxbows and twists in the Mississippi, as well as slowly moving areas and backwaters in the habitats where the Mississippi connects with White Oak Lake. Contact between crude oil and shorelines is also likely to result in mixing of mineral particles into the crude oil, which could then be deposited to sediments as aggregates of oil and mineral in larger droplets or globules. If not recovered, these aggregates could move downstream with bedload until a stable depositional environment was reached. Low molecular weight aromatic hydrocarbons would be expected to dissolve into the water column of White Oak Lake, where they could adsorb onto suspended sediment and organic matter.	LESS	MORE
Shoreline and Riparian Areas	Both light and heavy oil would travel downstream from the release location. Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, but would be thinner and less persistent where they contacted shorelines and riparian habitat. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet (and possible enter White Oak Lake). For heavy oil, stranding on shore would be the primary fate. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation. Flooding of riparian and wetland habitats in spring could lead to stranding of crude oils in these habitats, with heavy crude oil likely to be deposited as patties or tar balls, which would be persistent. This is in contrast to light crude oil which would be deposited as a thin layer or sheen.	LESS	MORE

Table 7-56 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Ball Club

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Ball Club	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Aquatic Plants	The Mississippi River and White Oak Lake support emergent, floating and submerged aquatic plants. Where they occur, floating aquatic plants would be expected to be killed if contacted by a floating oil slick. Submerged aquatic plants would be less vulnerable. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem was oiled). However, given the extent of predicted oiling in White Oak Lake in spring, death of emergent plants from contact with crude oil, particularly the lighter crude oil type, is also possible.	MORE	LESS
Benthic Invertebrates	Environmental effects on benthic invertebrates would be limited to areas affected by the released oil. In the short-term, the low viscosity of light crude oil would result in greater potential for oil entrainment as fine droplets, as compared to heavier blends. This would enhance dissolution of low molecular weight aliphatic and aromatic hydrocarbons into water (with resulting acute toxicity), in addition to promoting oil-particle interaction and potential deposition of oil to sediment. For heavy crude oil, there would be less potential for dissolution of hydrocarbons into the water, but greater long-term potential for deposition of tar balls and patties as a result of oil interaction with sediment. These could accumulate in depositional areas, resulting in chronic effects on benthic invertebrates.	MORE	LESS
Fish	Environmental effects on fish would be limited to areas affected by the released oil. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column. This would enhance the dissolution of potentially toxic fractions of the light oil into the water column. As a result, the potential for acute toxicity to fish due to narcosis would be greater for the light oil than for heavy oil. Potential chronic effects on fish eggs and embryos (e.g., blue sac disease) could also occur, but would be most likely to occur in spring and early summer, when most species spawn. The potential for phototoxicity, caused by an interaction of ultraviolet light with PAHs accumulated in fish tissues, would be greatest in summer due to high light intensity and long day length.	MORE	LESS

Table 7-56 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Ball Club

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Ball Club	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Semi-Aquatic Wildlife Receptors			
Amphibians and Reptiles	Environmental effects on amphibians and reptiles would be limited to areas affected by the released oil. Light crude oil is expected to travel farther downstream under spring and summer conditions than heavy crude oil, but would be thinner and less persistent on the water. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. Flooding of riparian habitat in spring could lead to stranding of crude oils in this habitat. Within these habitats, oiling effects on adults, juveniles, and eggs could potentially be observed. Higher potential would exist for effects on amphibians than for turtles, which appear to be somewhat tolerant of external oiling. Dormancy of amphibians and reptiles in winter and early spring means exposure to oil released at this time of year could be negligible, and adverse environmental effects unlikely.	MORE	LESS
Birds	Mortality of oiled aquatic and semi-aquatic birds would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil (for the three flow conditions modeled), so environmental effects could be more spatially extensive for light crude oil types. During the spring high flow season, many migratory birds would be returning to riverine and lacustrine habitats in Minnesota, or migrating through these areas on their way to breeding habitats farther north. As such, oiling of birds in White Oak Lake in spring could be the primary outcome of a release of light oil. Few birds are present in winter, so effects would be minimal in that season.	MORE	LESS
Semi-aquatic Mammals	Mortality of oiled semi-aquatic mammals would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil in all seasons, and spreading of the light crude oil into White Oak Lake is also possible under spring high flow conditions. Therefore, effects to semi-aquatic mammals could be more spatially extensive for light crude oil types. Adverse effects on mink and otter would be particularly severe in winter, due to the effects of oil in the insulating properties of fur, in combination with cold water temperatures. However, muskrat and beaver might be spared due to their lower activity levels in winter.	MORE	LESS

Table 7-56 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Ball Club

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Ball Club	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Human and Socio-Economic Receptors			
Air Quality	Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns. Light crude oils typically contain more VOCs than heavier crude oils, although the VOC content of diluted bitumen may be similar to that of light crude oil, depending on the type and quantity of diluent used in its manufacture. Air quality in the vicinity of the oil release would be most affected within the first 24 hours of an oil release. Light crude oil is likely to be transported farther downstream within 24 hours than the heavy crude oil, and could also enter White Oak Lake under spring high flow conditions. As a result, environmental effects on air quality are predicted to be more spatially extensive for light crude oil types. Under winter conditions, cold temperatures, ice cover and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS
Human Receptors	Typical human health effects associated with short-term inhalation of VOCs from crude oil releases include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain; fatality is unlikely. Residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most volatile hydrocarbons would be lost within 24 hours following a release. The communities of Ball Club and Zemple, Minnesota were identified through the HCA analysis as "other population areas". The human receptors most likely to be exposed to VOCs under this hypothetical crude oil release scenario would be located in Ball Club, or in isolated farms and country homes close to the Mississippi River, within about 5 to 10 miles of the release point. Under certain circumstances, the light crude oil could be carried farther downstream, and/or enter into White Oak Lake, resulting in potential exposure of residents of Zemple to VOCs. Under winter conditions, cold temperatures, ice cover and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS

Table 7-56 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Ball Club

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Ball Club	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Public Use of Natural Resources	Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Light crude oil is predicted to be transported farther downstream than heavy crude oil following a release, affecting a larger area and potentially interrupting public use of natural resources over a larger area. No drinking water HCAs were identified along the path of the release. However, some homes are located along the trajectory of a predicted release and could rely on groundwater as a drinking water source. In the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. It is unlikely that a crude oil release to the Mississippi River would result in adverse health effects to consumers of drinking water. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. In the event that the light crude oil was to enter White Oak Lake during the spring high flow season, it could affect the early development of wild rice plants, potentially affecting the productivity and utilization of this resource.	MORE	LESS

7.4 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL AT THE SANDY RIVER CROSSING

The proposed pipeline is expected to cross under the Sandy River approximately 3.4 miles northeast of McGregor, Minnesota and 0.2 miles north of Highway 210. Downstream of the proposed crossing the Sandy River passes through riparian wetlands, agricultural lands and wooded areas, as well as flowing through several lakes before it joins the Mississippi River at the northwest side of Big Sandy Lake. The main river channel at the Sandy River crossing is approximately 15 to 30 ft wide, and shows evidence of having been channelized, presumably for agricultural drainage purposes, within what was formerly a broad meandering floodplain (Chapters 3.0 and 4.0).

As identified in Chapter 4.0, the Sandy River flows through McGregor and Grayling WMAs of the Tamarack Lowlands Subsection. The subsection is a low-lying area of the Northern Minnesota Drift and Lake Plains Section within the greater Laurentian Mixed Forest Province (MN DNR 2016i). The Tamarack Lowlands is characterized by flat and rolling hills and lowland hardwood and coniferous forest cover (MN DNR 2006). The river flows about 1 mile north of populated sections of McGregor, and is about one half mile north of the airport, where it crosses Minnesota Highway 65.

7.4.1 Description of the Freshwater Environment

The Sandy River flows west through several marshy areas for approximately 6.2 miles before passing through two small lakes (Steamboat Lake and Davis Lake). Below these lakes the river turns to the northwest and becomes wider (an average of 53 ft during low flow conditions and 270 ft during high flow conditions). It then passes through Flowage Lake and Sandy River Lake before entering Big Sandy Lake, which supports considerable cottage development. A short distance below the outlet to Big Sandy Lake, the Sandy River merges with the Mississippi River (Smude 2013), which flows southwest, towards Palisade, Minnesota.

The seasonal extent or surface area of Steamboat, Davis, and Flowage lakes varies depending on river flow condition. During low and average river flow conditions, the area of Steamboat Lake is approximately 0.036 square miles, and during high river flow conditions the area is typically 0.065 square miles. During low and average river flow conditions, the area of Davis Lake is approximately 0.07 square miles, and during high river flow conditions the area is typically 0.117 square miles. During low river flow conditions, Sandy River does not join Flowage Lake until approximately 7 miles north of Davis Lake. Under high river flow conditions, the river becomes lake-like after approximately 3.5 miles.

The most common land uses in the Tamarack Lowlands Subsection are forestry, tourism, and outdoor recreation, along with some agriculture and peat mining (MN DNR 2006). Game fish include walleye, lake trout, and northern pike. Less sought-after fish include white sucker and yellow perch (MN DNR 2016j). The Tamarack Lowlands Subsection provides important wintering

areas for boreal birds in times of food shortage and is home to a predicted 69 SGCN. These include birds (51 species), fish (3 species), insects (5 species), mammals (4 species), mollusks (2 species), reptiles (4 species) and spiders (1 species) (MN DNR 2006). Of these species, 16 are afforded federal or state endangered, threatened, or of special concern status (MN DNR 2006; MN DNR 2016d). It is foreseeable that some of these SGCN could utilize aquatic habitats along the Sandy River and its associated lakes. The McGregor and Grayling Wildlife WMAs are home also to deer, mink, muskrat, white-breasted nuthatch, hairy woodpecker, sandhill crane, woodcock, sharp-tailed grouse, Canada goose, mallard, swamp sparrow, gray catbird and gray wolf (MN DNR 2006, MN DNR 2016k, MN DNR 2016l).

Several access points downstream from the proposed pipeline crossing location were visited in May, 2016, to provide additional insight into baseline environmental conditions for the Sandy River. Representative site photographs are provided in Figure 7-18 through Figure 7-21. Field observations are summarized in Table 7-57.

Table 7-57 Environmental Characteristics Observed at Selected Access Points on the Sandy River in May 2016

Access Point	Latitude Longitude	Notes
Sandy River at Highway 65, 4 miles downstream of pipeline crossing	46.6291 -93.3174	*Habitat Description:* this crossing is an excavated ditch with very broad, flat floodplain dominated by wet/sedge meadow and shrub Swamp. Dominant plant species are lake bank sedge and several species of willow (especially pussy willow). Quality of vegetation in the area is generally good to very good. *Wildlife observed:* mallard, red-wing blackbird, American toad, warbler sp.
Sandy River at boat landing, 8 miles north of McGregor, 19 miles downstream of pipeline crossing	46.7239 -93.3036	*Habitat Description:* area is a broad flowage of the impounded Sandy River. Water clarity is very good with abundant submerged vegetation. The water edge includes emergent marsh (river bulrush abundant) that transitions into willow shrub swamp and floodplain/terrace forest. Surrounding upland areas are mesic oak forest. Vegetation quality is generally good to very good. *Wildlife observed:* American toad, mallard, Canada goose, northern oriole, hairy woodpecker.
Sandy River at Big Sandy Lake, 28 miles	46.7884 -93.3188	*Habitat Description:* at Big Sandy Lake outlet dam. Lake fringe includes relatively narrow band of emergent marsh vegetation

Access Point	Latitude Longitude	Notes
downstream of pipeline crossing		(cattail-dominated), which then transitions into a narrow band of wet meadow that includes a mix of desirable native species and invasive/nonnatives (phragmites and reed canary grass). Floodplain/terrace forest vegetation occurs along the shoreline that rises quickly from the water. *Wildlife observed:* beaver, osprey, water boatmen (Family Corixidae; aquatic insect).

7.4.2 High Consequence Area Assessment for the Sandy River, MN

As defined in Section 6.3, HCAs include populated areas, drinking water source areas, ecologically sensitive areas, and commercially navigable waterways. AOIs include Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks).

Under low flow conditions, floating plumes for both oil types are predicted to end before they reach Steamboat Lake, but could pass McGregor, Minnesota. Bakken crude oil was predicted to flow farther downstream than the CLB under average and high flow conditions, but both oils passed the same number of HCAs during average and high flow seasons (i.e., McGregor, Minnesota and one environmentally sensitive area, Table 7-58).

The Sandy River flows through several protected areas and environmental AOIs. Modeling demonstrated that under low flow conditions, floating oil of both types passed the same AOIs, including the McGregor 8 site of biodiversity significance, Steamboat Lake, and the Grayling Marsh and McGregor WMAs. Under average flow conditions, floating oil was predicted to pass a similar number of AOIs in addition to Davis Lake. Under high flow conditions, Bakken crude oil was predicted to pass the same AOIs and also reach Flowage Lake, which is a sensitive lake shore and wild rice lake, and Big Sandy Lake, which is military land (Table 7-59). The HCAs and AOIs are shown in Figure 7-22.

Table 7-58 HCAs Potentially Affected by a Release of CLB and Bakken Crude Oil at the Sandy River Crossing Location

HCA Type	HCA Subtype	Description / Locations
Population Area	Other	McGregor, MN
Environmentally Sensitive Area	N/A	N/A

7.4.3 Selection of Key Ecological and Human Environment Receptors for Sandy River

Taking into account environmental characteristics of the Sandy River, the potential interactions of released crude oil with key ecological and human environment receptors were screened to identify key receptors for the subsequent environmental effects analysis. The rationale and results of this screening step are provided in Table 7-60.

Table 7-60 Key Ecological and Human Environment Receptors for the Sandy River

Receptor	Relevance for Inclusion as an Environmental Receptor for the Sandy River Scenario	Selected (Y/N)
Terrestrial Receptors		
Soils	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River with no holdup of oil on land. Any oil that reaches soil would be physically remediated to established standards.	N
Groundwater	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River with no holdup of oil on land. In the event of an actual oil release, effects on groundwater quality would be localized and/or negligible.	N
Terrestrial Vegetation	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River with no holdup of oil on land. Any oil that reaches soil would be physically remediated and vegetative cover would be restored as part of the cleanup process.	N
Aquatic Receptors		
Rivers (Sandy River)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River with subsequent physical transport downriver of floating oil.	Y
Lakes (Steamboat, Davis, Flowage lakes)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River with subsequent physical transport into Steamboat Lake, Davis Lake and Flowage Lake.	Y
Sediment	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River upstream of Steamboat, Davis and Flowage lakes with subsequent physical transport downriver. This allows potential interaction and/or deposition of crude oil residues to sediments.	Y
Shoreline and Riparian Areas	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River upstream of Steamboat, Davis and Flowage lakes with subsequent physical transport downriver. This allows potential interaction with shoreline and riparian habitat.	Y

Table 7-60 Key Ecological and Human Environment Receptors for the Sandy River

Receptor	Relevance for Inclusion as an Environmental Receptor for the Sandy River Scenario	Selected (Y/N)
Wetlands	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into Sandy River upstream of Steamboat, Davis and Flowage lakes with subsequent physical transport downriver and potential interaction with wetlands along the river and lakes.	Y
Aquatic Plants	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Sandy River upstream of Steamboat, Davis and Flowage lakes with subsequent physical transport downriver and potential interaction with plants. Aquatic plants are present in Sandy River and associated lakes, and riparian and wetland habitats.	Y
Benthic Invertebrates	High. The Sandy River and Steamboat, Davis and Flowage lakes support benthic invertebrate communities.	Y
Fish	High. The Sandy River and Steamboat, Davis and Flowage lakes support fish communities.	Y
Semi-Aquatic Wildlife Receptors		
Amphibians and Reptiles	High. The Sandy River and lake systems downstream of the release location support aquatic and semi-aquatic amphibians and reptiles.	Y
Birds	High. The Sandy River and lake systems downstream of the release location support a diverse bird community.	Y
Semi-aquatic Mammals	High. The Sandy River and lake systems downstream of the release location support semi-aquatic mammals.	Y
Human and Socio-Economic Receptors		
Air Quality	High. The community of McGregor, Minnesota is approximately 3.3 miles northeast the hypothetical release location. The Sandy River, Steamboat Lake and Davis Lake are also bordered by homes and used for recreational activities (e.g., hunting, fishing, boating, canoeing). Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns.	Y
Human Receptors	High. The Sandy River, Steamboat Lake and Davis Lake are sporadically bordered by homes and used for many recreational activities (e.g., hunting, fishing, boating, canoeing). Effects on air quality or the presence of crude oil residues in river water and riparian habitat have the potential to temporarily affect human health.	Y
Public Use of Natural Resources	High. The Sandy River, Steamboat Lake and Davis Lake are sporadically bordered by homes and used for many recreational activities (e.g., hunting, fishing, boating, canoeing). Effects on air quality, water quality, or the presence of crude oil residues in rivers, lakes and riparian habitat could potentially disrupt public use of natural resources (e.g., drinking water supplies).	Y

7.4.4 Modeled Conditions at the Release Location

A description of key modeling assumptions for the environmental effects analysis for the Sandy River scenario is provided in this section. The OILMAP Land software was used by RPS ASA to simulate hypothetical releases of CLB and Bakken crude oils into the Sandy River (Chapter 4.0) for a 24 hour period. The maximum simulation duration using OILMAP Land was 24 hours, as it was assumed that emergency response measures to prevent farther downstream transport of released oil would be in place within that length of time. Symbols on the drawings indicate the predicted trajectory during river seasonal flow condition (high corresponding to spring freshet, average corresponding to summer-fall conditions, and low corresponding to winter flow under ice).

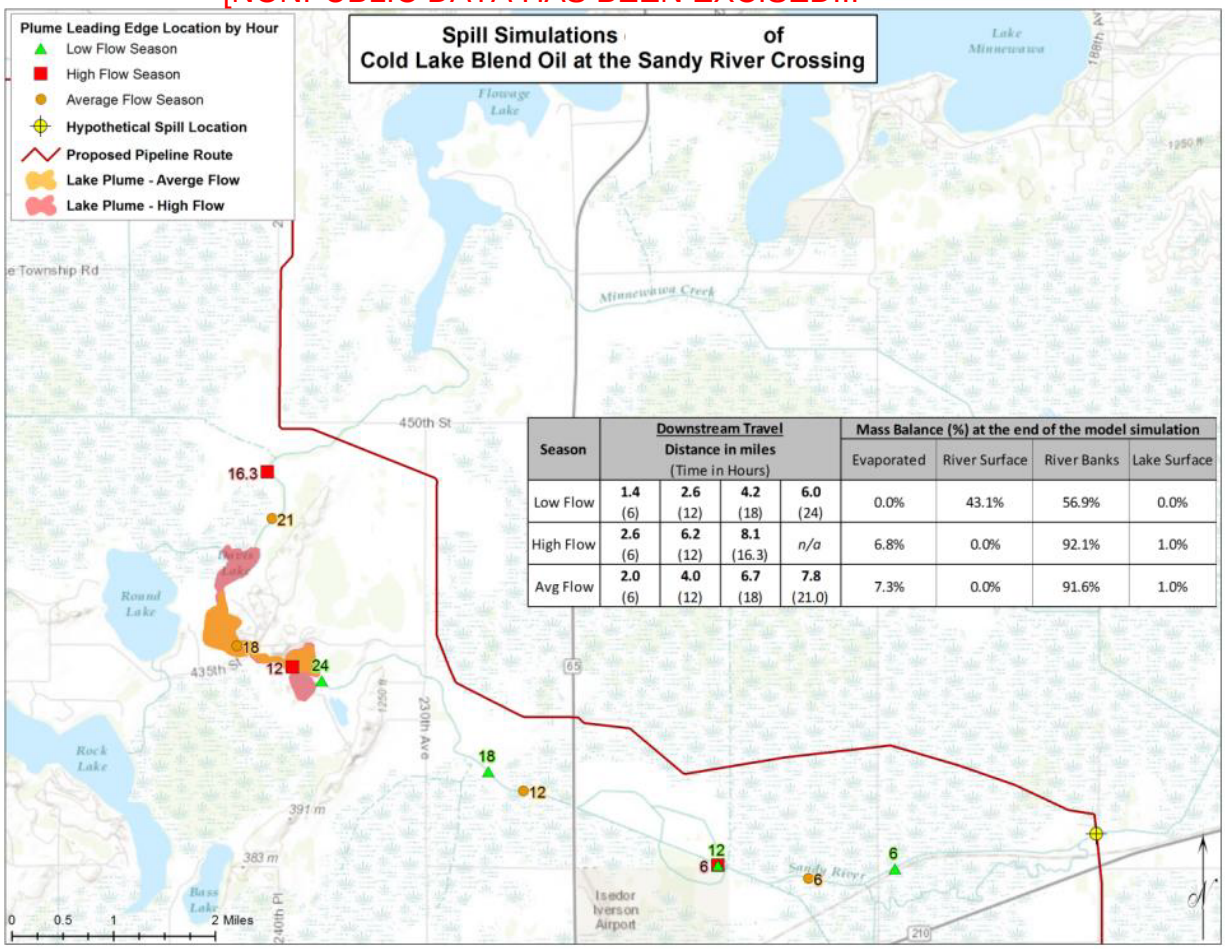
The two crude oil types provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (CLB/CLWB, heavy diluted bitumen crude oil types having higher viscosity and density). Seasonal variations in river flow velocity, temperature, wind speed, and snow and ice cover were all considered at the release location. A summary of key variables is provided in Table 7-61.

Table 7-61 Environmental and Hydrodynamic Conditions for the Three Modeled Periods at the Sandy River Crossing

Season	Month	Air Temperature (°C)	Wind Speed (m/s)	Average River Velocity (m/s)
Low Flow (Winter)	March	-3.07	4.21	0.13
Average Flow (Summer/fall)	July	19.96	3.50	0.24
High Flow (Spring)	April	5.00	4.73	0.35
NOTE: A velocity of 1 m/s is equivalent to 2.25 miles per hour.				

The highest flow velocity of the Sandy River coincides with the spring freshet (i.e., April), a result of rising temperatures and snowmelt. Average flow would typically occur in summer and fall seasons. July, the month with the warmest temperature was selected to represent the maximum amount of evaporation. The lowest flow rate occurs in winter (i.e., January-March), and was typified by freezing conditions and probable ice cover on water.

The crude oil release volume was calculated as a full bore rupture, with a maximum time to response in the pipeline Control Center of 10 minutes, followed by a 3-minute period to allow for valve closure. The release volume therefore represents the volume of oil actively discharged in the period of time required to detect and respond to the event (taking into consideration the pipeline diameter, pipeline shutdown time, pipeline design flow velocity), followed by the volume of oil lost due to drain-down of the elevated segments of pipeline. The maximum 13-minute response time to valve closure is an Enbridge standard for safe operations and leak



detection. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown and full valve closure in the affected pipeline section. While 13 minutes is the maximum time for valve closure, this is a conservative assumption, since a response through to valve closure is expected to occur in less than 13 minutes in a full bore rupture leak scenario. Based on these assumptions, the site-specific hypothetical release volume was estimated of Bakken, CLB, or CLWB crude oil.

7.4.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils

A summary of the predicted downstream trajectory and mass balance of Cold Lake and Bakken crude oils, under the three seasonal scenarios, is illustrated in Figure 7-23 and Figure 7-24, respectively. These simulations are assumed to provide bounding conditions for a release of heavy or light crude oil types. The fate of most types of crude oil, if released, would lie within the envelope of predictions for the Cold Lake and Bakken crude oil types. The Cold Lake crude oil was assumed to be CLB for the high flow and average flow scenarios, and to be CLWB for the low flow scenario. Details about the predicted downstream transport are provided in the following sections.

As noted in Section 7.5.3, the maximum simulation duration using OILMAP Land was 24 hours, as it was assumed that emergency response measures to prevent continued downstream transport of released oil would be in place within that length of time. Symbols on the drawings indicate the river seasonal flow condition (high corresponding to spring freshet, medium corresponding to summer-fall conditions, and low corresponding to winter flow under ice). Numbers associated with the symbols indicate the predicted location of the leading edge of the released oil in the river after 6, 12, 18 or 24 hours. Numbers other than these (e.g., 16.3) indicate the time in hours of the predicted termination of downstream transport of the released oil due to adhesion or holdup of the oil along the river banks. Tables inserted within the Figures also provide information on the mass balance (i.e., oil remaining on the surface of the river, adhering to river banks, or evaporated to the atmosphere) of the released oil at relevant points in time after the start of the release.

Figure 7-24 Predicted Downstream Transport of Bakken Crude at the Sandy River Crossing Location

7.4.5.1 Sandy River Release During High Flow (Spring) Period

The OILMAP Land model transported oil downstream with these velocities to a point where all oil had evaporated and/or adhered to the shoreline. Under this high river flow scenario, CLB crude oil was predicted to travel a total of approximately 8.1 miles downstream, within 16.3 hours of the release. The CLB crude oil was predicted to be transported along the Sandy River, to then spread over the surfaces of both Steamboat Lake and Davis Lake (for a total area of 0.182 square miles and at a thickness of 0.004 inches [0.1 mm]), and then continue another 0.7 miles down Sandy River. Approximately 92.1% of the CLB crude oil was predicted to oil the shorelines of Sandy River, 1.0% to have spread over the surface of Steamboat and Davis lakes, and 6.8% to have evaporated into the atmosphere.

Bakken crude oil was predicted to be transported approximately 12.2 miles downstream, over the full 24-hour modeled period. The Bakken crude oil was predicted to be transported down the Sandy River, to then spread over the surfaces of both Steamboat Lake and Davis Lake (for total area of 0.182 square miles at a thickness of 0.00004 inches), and then continue another 3.5 miles in Sandy River before reaching Flowage Lake. Oil was predicted to spread very thinly (less than 0.00004 inches) over approximately 0.22 square miles of the surface of Flowage Lake. If left unmitigated, it is predicted that this spreading would continue to occur after 24 hours, covering a larger surface area of the lake. Approximately 37.0% of the Bakken crude oil was predicted to oil shorelines of Sandy River, 20.3% would have spread over the surface of Steamboat, Davis, and Flowage lakes, and 42.8% would have evaporated into the atmosphere.

Bakken crude oil was predicted to result in oiling 4.1 miles farther downstream, than the CLB crude oil (8.1 miles) under high flow river conditions. The difference in the extent of downstream transport was primarily the result of the differences in the shoreline and lake surface oil retention between the two oil types. CLB, the more viscous crude oil, would adhere to shorelines and spread as a thicker slick than the less viscous Bakken crude oil. Therefore, the same amount of Bakken would oil a greater length of shoreline and more lake surface, but at a lower slick thickness. While this result is logical, it is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point is oiled to its maximum holding capacity) as oil makes its way downstream, and the assumption that oil would spread evenly within lake. In the event of an actual release, the downstream extents of CLB and Bakken crude oils may be more similar, and the effects of CLB may extend farther downstream than presented, with patchy coverage. Due mostly to the lighter nature and higher volatile content, much more of the Bakken crude oil was predicted to evaporate (42.8%) than was predicted for the CLB crude oil (6.8%).

7.4.5.2 Sandy River Release During Average Flow (Summer-Fall) Period

Under average river flow conditions, CLB crude oil was predicted to travel a total of 7.8 miles downstream within 21 hours of the release. The CLB crude oil was predicted to be transported down the Sandy River, to then spread over the surfaces of both Steamboat Lake and Davis Lake (for total area of 0.106 square miles at a slick thickness of 0.004 inches), and then to continue another 0.7 miles down the Sandy River. Approximately 91.6% of the CLB was predicted to oil shorelines of Sandy River, 1.0% to have spread over the surface of Steamboat and Davis lakes, and 7.3% to have evaporated into the atmosphere.

Relative to the high river flow condition, the CLB crude oil was predicted to be transported a shorter distance downstream (0.3 miles). This was predominantly due to the longer duration of the scenario which allowed for more evaporation. Under both high and average flow conditions, oil was modeled to spread over the entire surface of both Steamboat and Davis lakes. However the area of the lakes was smaller in the average flow condition.

Under average river flow conditions, Bakken crude oil was predicted to be transported approximately 9.1 miles downstream over the 24-hour modeled period (Figure 7-24). The Bakken crude oil was predicted to be transported down the Sandy River, and to then spread over the surfaces of both Steamboat and Davis lakes (for total area of 0.106 square miles and at a thickness of 0.00004 inches). It was then able to continue another 2.05 miles down Sandy River. Approximately 25.6% of the Bakken crude oil was predicted to oil shorelines of Sandy River, less than 0.1% to spread over the surface of Steamboat and Davis lakes, 41.2% to have evaporated into the atmosphere, and 33.2% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, it is predicted that the remaining Bakken crude oil on the river surface would continue downstream, with weathering and oiling of shorelines continuing until all the oil is removed from the water surface.

The Bakken crude oil was predicted to be transported 3.1 miles less under summer-fall conditions when compared to the high river flow conditions. The lower river velocities of the average river flow condition prevented the oil from being transported as far downstream within the 24 hour simulation period. The Bakken crude oil evaporated less in the average flow condition (41.2 %) than the high flow condition (42.8%) due to the reduced surface area oiled. This was a result of smaller area of Steamboat and Davis lakes, and the reduced downstream transport. When compared to the CLB crude oil under average river flow conditions Bakken was transported 3 miles farther downstream before reaching the 24 hour model limit. Approximately 33.2% of the Bakken crude oil was predicted to remain on the river surface at the end of the simulation. If left unmitigated, it is predicted that the remaining Bakken crude oil on the river surface would continue downstream, with weathering and oiling of shorelines continuing until all the oil is removed from the water surface. The Bakken crude oil was able to travel farther downstream, under the same river velocities, due to differences in the shoreline and lake surface oil retention between the two oil types.

7.4.5.3 Sandy River Release During Low Flow (Winter) Period

Under winter conditions, it was assumed that the Sandy River and downstream lakes would be frozen (100% coverage of ice). It was assumed that CLWB crude oil would be released directly into the river from the pipeline under the riverbed, and that all oil would remain trapped under the ice. The ice cover would strongly limit or prevent evaporation of crude oil vapors to the atmosphere. Flow velocity for Sandy River during these winter conditions resulted in minimum river velocities during March.

Under low river flow conditions, CLWB crude oil was predicted to be transported a total of 6.0 miles downstream, over the full 24-hour modeled period. The CLWB crude oil was predicted to stop just before reaching Steamboat Lake. Approximately 43.1% of the CLWB crude oil was predicted to remain in the river below the ice, and the remaining 56.9% to have oiled the shorelines of Sandy River. Any CLWB remaining in the river after 24 hours would continue to move downstream, oiling shorelines and Steamboat Lake, if not intercepted by emergency response teams.

Relative to the high and average river flow conditions, the CLWB crude oil was predicted to be transported over a shorter distance during low river flow conditions, stopping before reaching Steamboat Lake. This was due to the reduced river velocities under the low river flow conditions.

Under low river flow conditions, Bakken crude oil was predicted to be transported a total of 6.0 miles downstream, over the full 24-hour modeled period to a point just before Steamboat Lake. Approximately 91.0% of the Bakken crude oil was predicted to remain in the river below the ice, and the remaining 9.0% to oil shorelines of Sandy River. If not intercepted by emergency response teams, the remaining Bakken crude oil in the river after 24 hours would be expected to move downstream, oiling shorelines and Steamboat Lake.

Relative to the high river flow conditions, the Bakken crude oil under low river flow was predicted to be transported 6.2 miles less downstream. Relative to the average river flow condition, the Bakken crude oil was predicted to be transported 3.1 miles less downstream. Under low river flow conditions, the shore types were assumed to be the same as the average flow condition. With the oil being transported at a slower speed, the 24 hour modeled time limit was reached at a distance that was shorter than that of the average river flow condition with oil remaining on the surface. With the Bakken crude oil below the ice of the river, no oil was allowed to evaporate from the surface. When compared to the CLWB oil under low river flow conditions, 47.9% more of the Bakken crude oil remained in the river and under the ice. This would provide only temporary storage of the oil, and oil would be expected to re-mobilize in response to changes in flow velocity, and particularly during the spring breakup of ice. This was due to the lower shoreline oil retention between the two oils. For this reason the Bakken crude oil was predicted to have greater mobility under the ice in winter.

7.4.6 Qualitative EHHRA for the Sandy River

In this section the likely environmental effects of a crude oil release at the pipeline crossing location on the Sandy River are described. A worst case crude oil release from a main-line pipeline, such as described here, would be an unlikely event (Chapter 4.0). The proposed pipeline could carry a variety of crude oil types, ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB). Therefore, the following discussion is based on the likely environmental effects of a crude oil release on relevant ecological and human environment receptors (identified in Section 7.5.3), using the predicted geographic extent of effects of released Bakken or CLB crude oil types over the 24 hour simulations as bounding conditions. Effects of season (including temperature, river flow conditions, and receptor presence/absence and sensitivity) as appropriate were also considered in the analysis. The rationale supporting the effects analysis, based on case studies describing the effects of crude oil releases on the various ecological and human environment receptors, was provided in Section 7.1 and Table 7-60.

7.4.6.1 Terrestrial Receptors

For this modeling scenario, the hypothetical release of crude oil is assumed to occur into the Sandy River, so that environmental effects on soils, terrestrial vegetation and groundwater quality are assumed to be localized, limited in spatial extent, and readily remediated using conventional clean-up techniques. The environmental effects of a crude oil release on land cover receptors are not considered further for this release scenario.

7.4.6.2 Aquatic Receptors

The aquatic environmental and ecological receptors that are most closely associated with the Sandy River, and Steamboat, Davis, and Flowage lakes are addressed in this section. These receptors include water and sediment quality in rivers and lakes, shoreline and riparian river bank habitat, wetlands, aquatic plants (including wild rice), benthic invertebrates, and fish.

If crude oil were to enter the Sandy River during the spring (high flow) or summer-fall (average flow) periods, it would be predicted to travel downstream and then enter and partially to fully cover the surfaces of Steamboat, Davis and Flowage lakes. As it traveled, crude oil would interact with vegetation and seasonal shoreline, the amount of which would vary depending upon season and water levels. During high flow conditions, the lakes have approximately one and a half to two times greater surface area than under average or low river flow conditions. Heavier crude oils could result in plumes on Steamboat and Davis Lake with a greater thickness than expected for lighter crude oils, but this would also tend to reduce the extent of overall downstream transport. Lighter oils could also enter Flowage Lake and could be found spread very thinly.

Based on a 24 hour model run, the OILMAP Land simulations suggest that crude oil could be carried between 2.0 and 12.2 miles downstream from the point of release during spring and summer-fall periods. For heavy oil, stranding on river banks would be the primary fate, with only small amounts of evaporative weathering of the oil occurring before the oil becomes stranded. However, for light oil the primary fate is evaporation with a moderate amount expected to remain on river banks or on the surface of Sandy River (under average flow conditions) or downstream lakes (under high flow conditions). Receding waters in the lakes in late summer could lead to further stranding of oil as riparian and wetland habitats drain.

The effects of crude oil release on benthic invertebrates and fish depend on characteristics of the released oil and environmental conditions at the time of the release. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column, meaning potentially toxic fractions of the light oils would more readily dissolve into the water column. As a result, the potential for acute toxicity to fish and invertebrates is often greater for light crude oil than for heavier oils. However, Sandy River is a low-gradient watercourse, and both Steamboat and Davis lakes are small water bodies, with limited fetch (and low potential for the formation of breaking waves on their

surfaces). Therefore, both light and heavy oils are likely to float on the water surface, with low potential for turbulence to entrain oil as fine droplets into the water column.

Acute toxicity to fish is commonly but not always observed in association with crude oil releases, and is an indicator that, at least briefly, concentrations of dissolved hydrocarbons (particularly mono-aromatic hydrocarbons, some low molecular weight PAHs, and short-chain aliphatic hydrocarbons) are sufficiently high to cause acute toxicity due to narcosis. Sandy River is a small, shallow watercourse at the hypothetical release location, and even though flow in the river is unlikely to entrain small crude oil droplets into the water column, the very limited dilution provided by this river means that there is high potential for toxicity to fish and other aquatic life. While the large volume of water flow associated with the spring period freshet may dilute and limit the maximum dissolved hydrocarbon concentration in Sandy River as compared to periods of lower water flow in summer, it is unlikely that this would reduce effects to fish within the lake systems given the predicted crude oil coverage on the water surface in both seasons. As a result, narcotic effects on fish and benthic invertebrates are likely in all seasons. There would also be potential for phototoxicity, caused by an interaction of ultraviolet light with PAHs accumulated in fish tissues. This potential would be greatest in summer, due to high light intensity and long day length, and lowest in winter due to ice and snow cover, shorter day length, and lower sun angles. There would also be potential for chronic effects of released crude oil on fish eggs and embryos (i.e., induction of deformities or mortality collectively termed blue sac disease). Many fish species spawn in the spring and early summer. The eggs and embryos of these species could be exposed to total PAH concentrations in the river water that could be sufficiently high to induce deformities or cause mortality.

The non-turbulent flow characteristics of Sandy River suggest that entrainment of crude oil as fine droplets in the water column is unlikely. Therefore, there is low potential crude oil to interact with suspended sediment particles in the water column, resulting in the formation of OPAs. However, the released oils could still contact organic matter and sediment particles along shorelines, and some accumulation of both light and heavy oils in depositional areas is likely as a result of interactions between released oil and shorelines. Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release.

For a hypothetical release under spring freshet conditions, it is likely that most aquatic plants would still be dormant or submerged, and that environmental effects on this receptor type would be minimal. However, the Sandy River to Flowage Lake system supports a wide range of aquatic plants and where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Submerged aquatic plants would be less vulnerable, as they would be exposed primarily to dissolved hydrocarbons, and are not considered likely to be among the most sensitive groups of aquatic biota to such exposure. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem could be oiled). However, flooded riparian areas and wetland habitats (especially during spring periods when the lakes are at their maximum surface area) would also be exposed to the released oil,

and if not properly remediated, crude oil residues could kill plants in these areas. This could affect the biological integrity and productivity of the habitat, and potentially lead to erosion and further damage to the habitat.

Wild rice is an emergent aquatic plant of biological and cultural importance in Minnesota and occurs in many areas between the predicted point of release and Flowage Lake. Wild rice provides a food source and nesting cover for many birds, and is also harvested as a food source by people in the area. Given the extent of predicted oiling in spring and summer seasons, loss of emergent plants from contact with crude oil could be expected.

Under low flow conditions, it was assumed that Sandy River and its associated lakes would be frozen (100% coverage of ice). Based on the 24 hour simulations, both bounding oil types were predicted to be transported a total of 6.0 miles downstream. More of the light oil (91%) is predicted to remain potentially mobile under the ice after 24 hours than for the heavy oil (43%), with the balance of the oils assumed to be trapped in hollows under the ice, or close to the river margins, between the ice and the river sediment. For both oil types, the winter ice would effectively inhibit evaporation, while providing greater potential for dissolution into the water column during the period of lowest dilution flow. Therefore, a release in winter could cause mortality to fish due to narcosis. This result would be more likely for the light crude oil, which remain at the ice-water interface, than for the heavy crude oil, which would tend to remain in thicker localized accumulations along the banks. Fish eggs and larvae would generally not be present during the winter. Both crude oil types could accumulate in sediment, and both would be subject to re-mobilization with spring breakup of the ice, and increasing water flow rates.

7.4.6.3 Semi-Aquatic Wildlife Receptors

Habitats along Sandy River, Steamboat Lake, Davis Lake and Flowage Lake support semi-aquatic wildlife receptors including amphibians (e.g., frogs, salamander), reptiles (e.g., turtles, snakes), semi-aquatic birds (e.g., ducks, geese, cranes) and semi-aquatic mammals (e.g., muskrat, otter). While individual animals may be affected by exposure to released oil in the immediate area of the river, regional populations of these animals will be robustly supported by extensive wetland and aquatic habitats within the region. Details on predicted environmental effects for amphibians and reptiles, birds and mammals are provided below.

7.4.6.3.1 Amphibians and Reptiles

Crude oil released to the Sandy River during the spring (high flow) and summer-fall (average flow) periods is predicted to travel downstream as it then enters and covers or partially covers the surfaces Steamboat, Davis and Flowage lakes. Within these habitats, oiling effects on amphibians (adults, juveniles, and eggs) and reptiles would be observed. Higher potential would exist for effects on amphibians (i.e., physical effects of oiling, as well as narcotic effects similar to fish and benthic invertebrates) than for adult turtles, which appear to be somewhat tolerant of external oiling. A release of light crude oil during the spring would likely have a greater effect than in summer due to the greater predicted transport distance, and interaction with more

riparian and wetland habitats than under average flow conditions. Reptiles like lizards and snakes are primarily terrestrial species and are less intimately associated with aquatic environments. As a result, exposure of these animals to released crude oils would be limited.

Amphibians and reptiles undergo a winter dormancy period when temperatures drop below approximately 41 to 45°F. At this time, amphibians and turtles typically bury themselves in river bottom substrates. Therefore, during the winter (and likely up until April or May when winter ice is gone), these organisms would have very little exposure to released oil moving on the water surface or within the water column.

7.4.6.3.2 Birds

Aquatic and semi-aquatic birds are those that use rivers, lakes, wetlands, and riparian areas as components of their habitats, particularly for nesting and feeding. These birds belong to a variety of guilds including but not limited to waterfowl, divers, gulls and terns, raptors, shorebirds, waders, and some songbirds. They have a variety of dietary preferences, including piscivory, insectivory, omnivory and herbivory.

If exposed to external oiling, the ability of birds to maintain body temperature may be compromised, leading to death as a result of hypothermia. Even if they survive their initial exposure to crude oil, the exposure may require an increase in metabolic rate to survive. In turn, this may compromise other life functions such as reproduction or growth. Birds that survive external oiling may experience toxicological stresses as a result of ingesting crude oil residues while preening or attempting to clean and restore the normal properties and functions of feathers. Birds can also transfer potentially lethal quantities of crude oil residue from their feathers to the external surface of eggs, resulting in death of developing embryos. Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species which leave their summer (and often breeding) habitat in the fall for wintering areas farther south where they can find open-water habitat. However, some birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available. Timely capture and rehabilitation of oiled birds may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, many migratory birds would be returning to riverine and lacustrine habitats in Minnesota, or migrating through these areas on their way to breeding habitats farther north. With cold water temperatures prevailing, aquatic and semi-aquatic birds contacted by crude oil are likely to die as a result of hypothermia. Animals in the affected river reach and lakes would be most affected. Animals upstream, farther downstream, or occupying other nearby habitats, would likely be less affected since emergency response measures to prevent or reduce farther possible downstream transport of oil would be in place within 24 hours of the release. Therefore, although mortality of some semi-aquatic birds is expected, large-scale population level effects are unlikely.

Environmental effects of a crude oil release in the summer period are likely to be of similar or lesser magnitude. Due to lower river flow rates, the size of the potentially affected river reach is smaller. With rising water temperatures, mortality of lightly oiled adult birds due to hypothermia becomes less likely than in the spring. However, in the early summer, environmental effects could include egg mortality due to transfer of oil from the feathers of lightly oiled adult birds in the nest. Chronic adverse effects on the health of birds that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while preening, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure.

In the winter months, ice cover on the Sandy River, and Steamboat, Davis and Flowage lakes, would strongly limit the opportunities for aquatic and semi-aquatic birds to occupy this habitat. In addition, released crude is predicted to remain beneath the ice cover of Sandy River and both Steamboat and Davis lakes. Therefore, adverse effects on the health of aquatic and semi-aquatic birds are not likely for a release of crude oil during the winter.

7.4.6.3.3 Semi-aquatic Mammals

While the semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, this assessment focuses particularly upon species that have a primary association with the aquatic environment, such as muskrat and beaver (herbivores), American mink (carnivore-piscivore) and river otter (piscivore). These species are at greater risk of exposure to an oil release in water than terrestrial mammals.

Effects to semi-aquatic mammals are typically described in terms of direct physical effects (e.g., hypothermia due to loss of insulation), direct toxicological effects (e.g., gastro-enteropathy caused by ingestion of crude oil residues while grooming oiled fur or ingesting food), and indirect effects caused by changes to habitat (e.g., land cover and food availability). The spatial extent along the Sandy River and associated lake systems where effects may occur, and the magnitude of effects, is related to the type of oil released and the season in which semi-aquatic mammal could be exposed. Effects to semi-aquatic mammals relate more to the amount of time spent in the water (and consequent exposure to physical oiling) than to dietary preferences. Timely capture and rehabilitation of oiled mammals may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, with cold water temperatures prevailing, semi-aquatic mammals contacted by crude oil are likely to die as a result of hypothermia. Animals in areas where there is predicted to be crude oil on the surface of the Sandy River and associated lakes could be affected. Animals upstream, farther downstream where there is no exposure, or occupying other nearby habitats, would likely be unaffected. Therefore, although mortality of some semi-aquatic mammals could be expected, large-scale population level effects are unlikely. Environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude to those associated with a release during spring freshet. Due to lower river flow rates, the size of the potentially affected river reach is smaller. With rising water temperatures, mortality of lightly oiled semi-aquatic mammals due to hypothermia is expected

to be less likely than in the spring. Chronic adverse effects on the health of semi-aquatic mammals that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while grooming, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure based on the 24 hour model run.

In the winter months, muskrat and beaver are likely to reduce their activity levels, although American mink and river otter would remain active. Animals that became oiled in the winter would be likely to rapidly die as a result of hypothermia

7.4.6.4 Human and Socio-Economic Receptors

Crude oils are complex mixtures of hydrocarbon compounds. Light crude oils typically contain more VOCs than heavier crude oils, although diluted bitumens may contain similar amounts of VOCs to light crude oils, depending upon the type and amount of diluent they contain. Air quality in the vicinity of a crude oil release, and along the downstream corridor, would be affected by the release of VOCs (such as benzene, which is often used as an indicator substance) primarily within the first 24 hours of an oil release. When crude oil is spread out as a thin layer, the rate at which the VOCs evaporate does not vary greatly with oil type. Therefore, air quality would be most affected by the initial concentration of benzene and other VOCs in the crude oil, the size of the area affected by the release, and weather conditions such as winds and atmospheric stability that will determine how quickly the VOCs disperse in air.

Typical human health effects associated with short-term (acute) inhalation of volatiles from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term or repeated skin contact with crude oil may result in dermatitis. The case studies (Section 7.1) do not reveal any instances of human fatality as a result of inhalation of crude oil vapor. Similarly, ATSDR (1995) report that there are no known instances of human fatality as a result of inhalation of vapor from fuel oils, which would be comparable to light crude oils.

The community of McGregor, Minnesota was identified through the HCA analysis as an "other populated area". The OILMAP Land modeling indicated that the leading edge of released crude oil would pass approximately one mile north of McGregor, although individual farms and homes are located within 100 ft of the Sandy River, Steamboat and Davis lakes. While no drinking water HCAs were identified along the path of the release, the homes located along the trajectories of predicted releases are likely to rely on groundwater as a drinking water source. In the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. Based upon case studies involving crude oil releases elsewhere, this process could take a few days to two weeks, but reports of crude oil releases affecting private wells are rare, making this an unlikely effect.

The potential for VOC inhalation exposures to the public would be greatest near and downwind from the release site and near to the Sandy River, Steamboat, Davis and Flowage lakes while the released oil is on the water surface. In the unlikely event of a crude oil release, residents in close proximity would become aware of a strong hydrocarbon odor. Most of the volatile

hydrocarbons would be lost within the first 24 hours following a release of crude oil. It is also expected that emergency response personnel would contact residents and advise them to evacuate. Actual or potential exposure to crude oil vapor may result in residents leaving, or being advised to leave their homes for a period of time while the emergency response takes place.

Relatively little has been published regarding the long-term effects of exposure by humans to an oil release. Health effects observed in residents and clean-up workers in the months following an oil release generally do not persist over the long term (Eykelbosh 2014). The International Agency for Research on Cancer (IARC 1989) determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans. Although toxicological effects from short-term exposure to volatile hydrocarbons are reversible when exposure is reduced, other health effects such as anxiety and depression may occur, and may persist, regardless of whether the individual was physically exposed to hydrocarbons.

Effects of a crude oil release on human receptors would be generally similar for the spring (high flow) and summer-fall (average flow) seasons. In summer, the warmer temperatures and slower river flow velocities in the summer would promote more rapid evaporation of volatile hydrocarbons in a smaller area. In the spring freshet period, higher river flow velocity would transport the released oil farther downstream within the first 24 hours, potentially resulting in lesser exposures, but to a larger number of people. The flow modeling suggests that the light crude oil (i.e., Bakken crude oil) is likely to be transported farther downstream within 24 hours than the heavy crude oil (Cold Lake diluted bitumen). As a result, a release of the light crude oil may affect a larger number of individuals than a release of the heavy crude oil type. Both Bakken crude oil and Cold Lake diluted bitumen are expected to contain similar overall amounts of volatile hydrocarbons, so differences related to the chemical characteristics of the released oil are likely to be minor.

No overland transport of released crude oil was modeled for this hypothetical release location. Infiltration of crude oil into soil and subsequently into groundwater would be limited. During the spring freshet period, the Sandy River could be susceptible to flooding and could overtop its banks and spread into the surrounding wetlands or farmland. A release of light and medium crude oils during this period would provide a potential pathway for oil deposition to soil in low-lying areas. Light and medium crude oils would be expected to become dispersed over a large area, and are readily biodegraded, so that persistent accumulation of these oil types in riparian areas or temporarily flooded farmland is unlikely. Heavy crude oils and diluted bitumen are more likely to be deposited as thicker layers of more persistent oil, and could require more active remediation of affected areas.

The Sandy River, as well as Steamboat, Davis and Flowage lakes provide recreational opportunities (e.g., fishing, hunting, boating, swimming, bird watching) downstream of the release location. Emergency response workers, in cooperation with public health and safety

officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. Fisheries regulators and public health officials typically close fisheries until it is confirmed through monitoring that fish consumption is not a threat to public health. This standard approach is an effective mitigation strategy to protect human receptors for contact with constituents in the oil.

7.4.6.5 Summary and Conclusions

Expected environmental effects to key ecological and human environment receptors after a hypothetical large crude oil release to the Sandy River area have been assessed. The proposed pipeline could carry a variety of crude oil types ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB). The discussion of expected environmental effects on receptors is based on these crude oil types as bounding conditions. Potential terrestrial and aquatic habitats, aquatic receptors, semi-aquatic wildlife receptors, human and socio-economic receptors were screened to identify those most likely to have interactions with released oil. Potential environmental effects to these receptor groups are summarized in Table 7-62.

Table 7-62 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Sandy River

Receptor	Expected Environmental Effects of Released Crude Oil to the Sandy River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Terrestrial Receptors			
Soils	It is assumed in the model that crude oil would enter directly into the Sandy River with no holdup of oil on land. In the event of an actual oil release, any oil on land would undergo prompt and effective remediation. Residual effects on plant communities, soil or groundwater quality are unlikely.	SAME	SAME
Groundwater		SAME	SAME
Terrestrial Vegetation		SAME	SAME
Aquatic Receptors			
Rivers (Sandy River)	Both light and heavy oil would travel downstream from the release location, entering the Sandy River. Lighter crude oils are predicted to travel farther downstream than heavier crude oils in spring and summer-fall conditions, but would be thinner and less persistent on the water. Both light and heavy crude oils are predicted to travel similar travel distances under winter conditions, although the heavy oil would be more likely to remain trapped along the edges of the rivers and lakes. The Sandy River is small, with a low gradient. Therefore, turbulent conditions that could entrain low-viscosity oil into the water column as fine droplets are unlikely to occur.	MORE	LESS
Lakes (Steamboat, Davis and Flowage Lake)	Both light and heavy oil would travel downstream from the release location, enter, and spread over the surfaces of Steamboat and Davis lakes, with the light crude oil also entering Flowage Lake under high flow conditions. Heavier crude oils would result in lake plumes with a greater thickness than expected for lighter crude. The lakes are small, with low fetch. Therefore, breaking waves that could entrain low-viscosity oil into the water column as fine droplets are unlikely to occur. In low flow winter conditions, neither type of crude oil was predicted to reach a lake within the 24 hour model simulation.	MORE	LESS

Table 7-62 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Sandy River

Receptor	Expected Environmental Effects of Released Crude Oil to the Sandy River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Sediment	Lighter crude oils are predicted to travel farther downstream than heavier crude oils in spring and summer conditions, with equal travel in winter months. The low mixing energy prevailing in the Sandy River system suggests that neither type of oil is likely to be entrained into the water column as fine droplets that could form OPAs. However, both oil types would interact with shoreline sediments, and the potential for oil to become absorbed into these sediments, or to sink in combination with adhering sand or silt particles, would remain. In this case, the light crude oil would be spatially more extensive, but also less persistent than the heavy crude oil. Under winter conditions, more of the heavy crude oil is predicted to become trapped along the margins of the rivers and lakes, and this oil is also likely to interact with sediment, resulting in mixing of oil and sediment. Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release.	LESS	MORE
Shoreline and Riparian Areas	Both light and heavy oil would travel downstream from the release location. Lighter crude oils are predicted to travel farther downstream than heavier crude oils in spring and summer-fall conditions, but would be thinner and less persistent on the water. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. For heavy oil, stranding on shore would be the primary fate. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation. Flooding of riparian and wetland habitats in spring could lead to stranding of crude oils in these habitats, with heavy crude oil likely to be deposited as patties or tar balls, in contrast to light crude oil which would be deposited as a thin layer or sheen. Receding waters in the lakes in late summer could lead to further stranding of oil as wetland habitat forms.	LESS	MORE
Aquatic Plants	The Sandy River and Steamboat, Davis and Flowage lakes support emergent, floating and submerged aquatic plants. Where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Lighter oils are predicted to spread more thinly and cover a larger are than heavier oils. Submerged aquatic plants would be less vulnerable. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem was oiled). However, given the extent of predicted oiling in Sandy River and associated lakes in spring and summer seasons, loss of emergent plants from contact with crude oil is to be expected.	MORE	LESS

Table 7-62 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Sandy River

Receptor	Expected Environmental Effects of Released Crude Oil to the Sandy River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Benthic Invertebrates	Environmental effects on benthic invertebrates would be limited to areas affected by the released oil. Heavy crude oil would have greater potential than light crude oil for deposition of tar balls and patties as a result of oil interaction with sediment. These could accumulate in depositional areas, resulting in chronic effects on benthic invertebrates.	LESS	MORE
Fish	Environmental effects on fish would be limited to areas affected by the released oil. The slow-moving character of the Sandy River is not likely to promote dissolution of low molecular weight hydrocarbons into the water. However, potential for toxicity to fish due to narcosis would exist for both types of oil, due to the small size of the river. Potential chronic effects on fish eggs and embryos (e.g., blue sac disease) could also occur, but would be most likely to occur in spring, when most species spawn. The potential for phototoxicity, caused by an interaction of ultraviolet light with PAHs accumulated in fish tissues, would be greatest in summer due to high light intensity and long day length.	SAME	SAME
Semi-Aquatic Wildlife Receptors			
Amphibians and Reptiles	Environmental effects on amphibians and reptiles would be limited to areas affected by the released oil. Light crude oil is predicted to travel farther downstream under spring and summer conditions than heavy crude oil, affecting a larger area of habitat. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. Flooding of riparian habitat in spring could lead to stranding of crude oils in this habitat. Within these habitats, oiling effects on adults, juveniles, and eggs could potentially be observed. Higher potential would exist for effects on amphibians than for turtles, which appear to be somewhat tolerant of external oiling. Dormancy of amphibians and reptiles in winter and early spring means exposure to oil released at this time of year could be negligible, and adverse environmental effects unlikely.	MORE	LESS

Table 7-62 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Sandy River

Receptor	Expected Environmental Effects of Released Crude Oil to the Sandy River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Birds	Mortality of oiled aquatic and semi-aquatic birds would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil, so environmental effects to birds could be more spatially extensive for light crude oil types as it enters lake habitat downstream of the hypothetical release location. Marshy areas along the Sandy River (especially McGregor and Grayling Wildlife WMAs), Steamboat, Davis and Flowage lakes provide the highest quality habitat for nesting birds. Cold water in the spring, in combination with greater downstream movement of released oil, suggests that environmental effects of released oil could be greatest for a light crude oil in spring, and of lesser magnitude for a heavy crude oil release. Few birds are present in winter, so effects would be minimal in that season.	MORE	LESS
Semi-aquatic Mammals	Mortality of oiled semi-aquatic mammals would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil, so environmental effects could be more spatially extensive for light crude oil types. Cold water in the spring, in combination with greater downstream movement of released oil, suggests that environmental effects of released oil could be greatest for a light crude oil in spring, and of lesser magnitude for a heavy crude oil release. In winter, adverse effects on mink and otter would be particularly severe, due to the effects of oil on the insulating properties of fur, in combination with cold water temperatures. However, muskrat and beaver might be spared due to their lower activity levels in winter.	MORE	LESS
Human and Socio-Economic Receptors			
Air Quality	Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns. Light crude oils typically contain more VOCs than heavier crude oils, although the VOC content of diluted bitumen may be similar to that of light crude oil, depending on the type and quantity of diluent used in its manufacture. Air quality in the vicinity of the oil release would be most affected within the first 24 hours of an oil release. Light crude oil is likely to be transported farther downstream within 24 hours than the heavy crude oil. As a result, environmental effects on air quality could be more spatially extensive for light crude oil types. Under winter conditions, cold temperatures, ice cover and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS

Table 7-62 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Sandy River

Receptor	Expected Environmental Effects of Released Crude Oil to the Sandy River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Human Receptors	Typical human health effects associated with short-term inhalation of VOC from crude oil releases include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain; fatality is unlikely. Residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most volatile hydrocarbons would be lost within 24 hours following a release. Light crude oil (Bakken crude oil) is likely to be transported farther downstream within 24 hours than the heavy crude oil (Cold Lake diluted bitumen). However, very few people live between Davis and Flowage lakes, and therefore the effect of this additional downstream movement in human receptors would be minimal. Under winter conditions, cold temperatures, ice cover and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	SAME	SAME
Public Use of Natural Resources	Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Light crude oil is predicted to be transported farther downstream than heavy crude oil following a release, affecting a larger area and potentially interrupting more public use of natural resources. No drinking water HCAs were identified along the path of the release. However, a number of homes are located along the trajectory of a predicted release and could rely on groundwater as a drinking water source. In the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. It is unlikely that a crude oil release to the Sandy River would result in adverse health effects to consumers of drinking water. However, recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route.	MORE	LESS

7.5 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE SHELL RIVER CROSSING AT TWIN LAKES, MN

The proposed pipeline route crosses the Shell River a number of times, and the hypothetical release location selected for modeling is located approximately 7.3 miles south of Park Rapids, Minnesota. This scenario captures a release of oil directly to a watercourse of medium width (70 to 120 ft) and moderately-flowing character that enters directly into the Twin Lakes. After flowing out of Lower Twin Lake, the Shell River meanders approximately 9.2 miles in a generally eastward direction before meeting the Crow Wing River, after which point the flow is generally to the south. There are 59 groundwater wells reported in the lower Shell River area, most of which are reportedly used for agricultural irrigation (MN PCA 2014). Irrigation circles are conspicuous around Park Rapids, to the east of Hubbard, and both south and east of the Twin Lakes. The presence of groundwater wells and residences with docks makes this site representative of inhabited areas that may be used recreationally, and for agriculture. In addition, this region is known to contain sensitive ecosystems. Therefore, the potential for crude oil from the release area into the Twin Lakes and subsequent transport farther down Shell River (and into Crow Wing River) was investigated. The Shell River is part of the Pine Moraines and Outwash Plains Subsection of the Northern Minnesota Drift and Lake Plains Section situated in the Laurentian Mixed Forest Province (MN DNR 2006).

7.5.1 Description of the Freshwater Environment

Upstream of the pipeline crossing location, the river channel is predominantly natural, with riparian marsh/fen/shrub swamp wetlands. Beginning approximately 2,070 ft upstream of the proposed pipeline crossing, the river enters a large wetland with bog elements. Within this area there is evidence of historical channel alteration (straightening), although below the proposed crossing the river channel appears to have reverted to a more natural channel. Approximately 3,000 ft south of the pipeline crossing, the wetland grades into Upper Twin Lake and has a conspicuous sandy outwash deposit. The open water area of Upper Twin Lake is about 4,150 ft long and 1,690 ft wide. The lake is surrounded by shrub swamp and fen, grading into marsh. Lower Twin Lake is slightly larger, being about 4,870 ft long and 1,830 ft wide, and having similar marginal wetlands. Both lakes have residential or cottage development around them but Lower Twin Lake is more intensively developed in this respect.

The Shell River is approximately 95 ft wide, approximately 1.5 ft deep, and passes through forested areas nestled between agricultural lands via a large marshy channel. The streambed is made up of loose sand and fine gravel. During the growing season much of the Shell River's streambed (33% to 40% coverage) supports macrophytes like cattails (MN PCA 2014). During the summer months, the Shell River can have low levels of dissolved oxygen, which is attributed to high water temperature and agricultural runoff (MN PCA 2014).

At the proposed crossing, the Shell River flows directly south where it reaches the Twin Lakes (Upper Twin Lake and Lower Twin Lake) about 0.6 miles downstream. The watercourse enters the

northern end of Upper Twin Lake before draining into a small reach that feeds Lower Twin Lake. The Twin Lakes cover a total area of approximately 0.75 square miles and are bounded by a number of homes with lake access. Both Upper and Lower Twin Lake have a diverse mix of aquatic plants including emergent (e.g., wild rice), floating (e.g., duckweed, waterlily) and submerged (e.g., Canada waterweed, flatstem pondweed, northern watermilfoil, coontail, and muskgrass) communities (Perleberg 2005; MN PCA 2014). Both lakes also provide habitat for numerous fish, including northern pike, walleye (a stocked species), perch, bass, and white sucker (MN PCA 2014). In addition to the recreational fishery, the bait fish industry is also well represented in the area (MN DNR 2006). The Shell River flows out of the northeastern edge of Lower Twin Lake and continues east through Huntersville State Forest, and south of Duck Lake. Here the river is wider (up to approximately 225 ft) than at the predicted release location. East of Duck Lake (which is surrounded by homes) and within the boundaries of the Huntersville State Forest and the Crow Wing Chain WMA, the Shell River merges with the Crow Wing River and flows south (MN DNR 2016g). The Shell and Crow Wing rivers provide opportunities for canoeing and fishing, with access along the river through the Huntersville State Forest (MN DNR 2016h). The average velocity of the Shell River changes with season, with slowest velocities (e.g., about 0.56 mph) expected during low flow periods in the winter, and greater velocities (e.g., about 1.2 mph) during the spring high flow period. Flow in the Shell River often exceeds the flow of the Crow Wing River (MN DNR 2016g).

The Pine Moraines and Outwash Plains is known to be home to 89 SGCN; these include birds (61 species), fish (4 species), insects (12 species), mammals (5 species), mollusks (2 species), and reptiles (4 species) (MN DNR 2006). Of these, 29 are afforded federal or state endangered, threatened, or of special concern status (MN DNR 2006; MN DNR 2016d). It is foreseeable that some of these SGCN could utilize aquatic habitats along the Shell River, Twin Lakes, and Crow Wing River.

Several access points downstream from the proposed pipeline crossing location were visited in May, 2016, to provide additional insight into baseline environmental conditions for the Shell River. Representative site photographs are provided in Figure 7-25 through Figure 7-28. Field observations are summarized in Table 7-63.

Figure 7-28 Crow Wing River and Riparian Habitat Approximately 47 Miles Downstream of Pipeline Crossing

Table 7-63 Environmental Characteristics Observed at Selected Access Points on the Shell River near Twin Lakes, MN, May 2016

Access Point	Latitude Longitude	Notes
South Twin Lake Water Access approximately two miles downstream of pipeline crossing	46.803341 -95.034157	*Habitat Description:* broad open water/floodplain area. Fringe of open water dominated by cattail marsh with floodplain meadow (dominated by nonnative reed canary grass) and shrub swamp fringe on the outside of emergent marsh. Black willow and green ash trees, as well as red osier dogwood are common on the floodplain fringe. *Wildlife observed:* yellow-headed blackbird, Baltimore oriole, osprey, red-wing blackbird, American robin, yellow throat
Mary Brown Water site access, #5 State Water Access approximately 25 miles downstream of pipeline crossing	46.7177 -94.9293	*Habitat Description:* broad, flat floodplain in this area with good quality emergent marsh and wet/sedge meadow dominant. Shrub swamp and terrace forest occur in lesser amounts. Water clarity is good with the submergent plant wild celery common. Wildlife observed: mallard, veery
Crow Wing River, Cottingham Co. Park, #11 State Water Access Site; approximately 47 miles downstream of pipeline crossing	46.5055 -94.8074	*Habitat Description:* river banks are somewhat steep and transition into forest with a blend of floodplain forest and terrace forest. Areas farther upslope include red maple, bur oak basswood, quaking aspen and others, with a diverse shrub and ground layer. *Wildlife observed:* eastern Kingbird, yellow warbler, fly catcher

7.5.2 High Consequence Area Assessment for the Shell River at Twin Lakes, MN

As defined in Section 7.0, HCAs include populated areas, drinking water source areas, ecologically sensitive areas, and commercially navigable waterways. Sensitive AOIs include Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks).

The locations of the various HCA (none of which are commercially navigable) and AOI near the hypothetical release location and the predicted trajectory of the floating oil are illustrated in Figure 7-29. Table 7-64 and Table 7-65 provide brief descriptions of the HCA and AOI for the Shell River hypothetical crude oil release location.

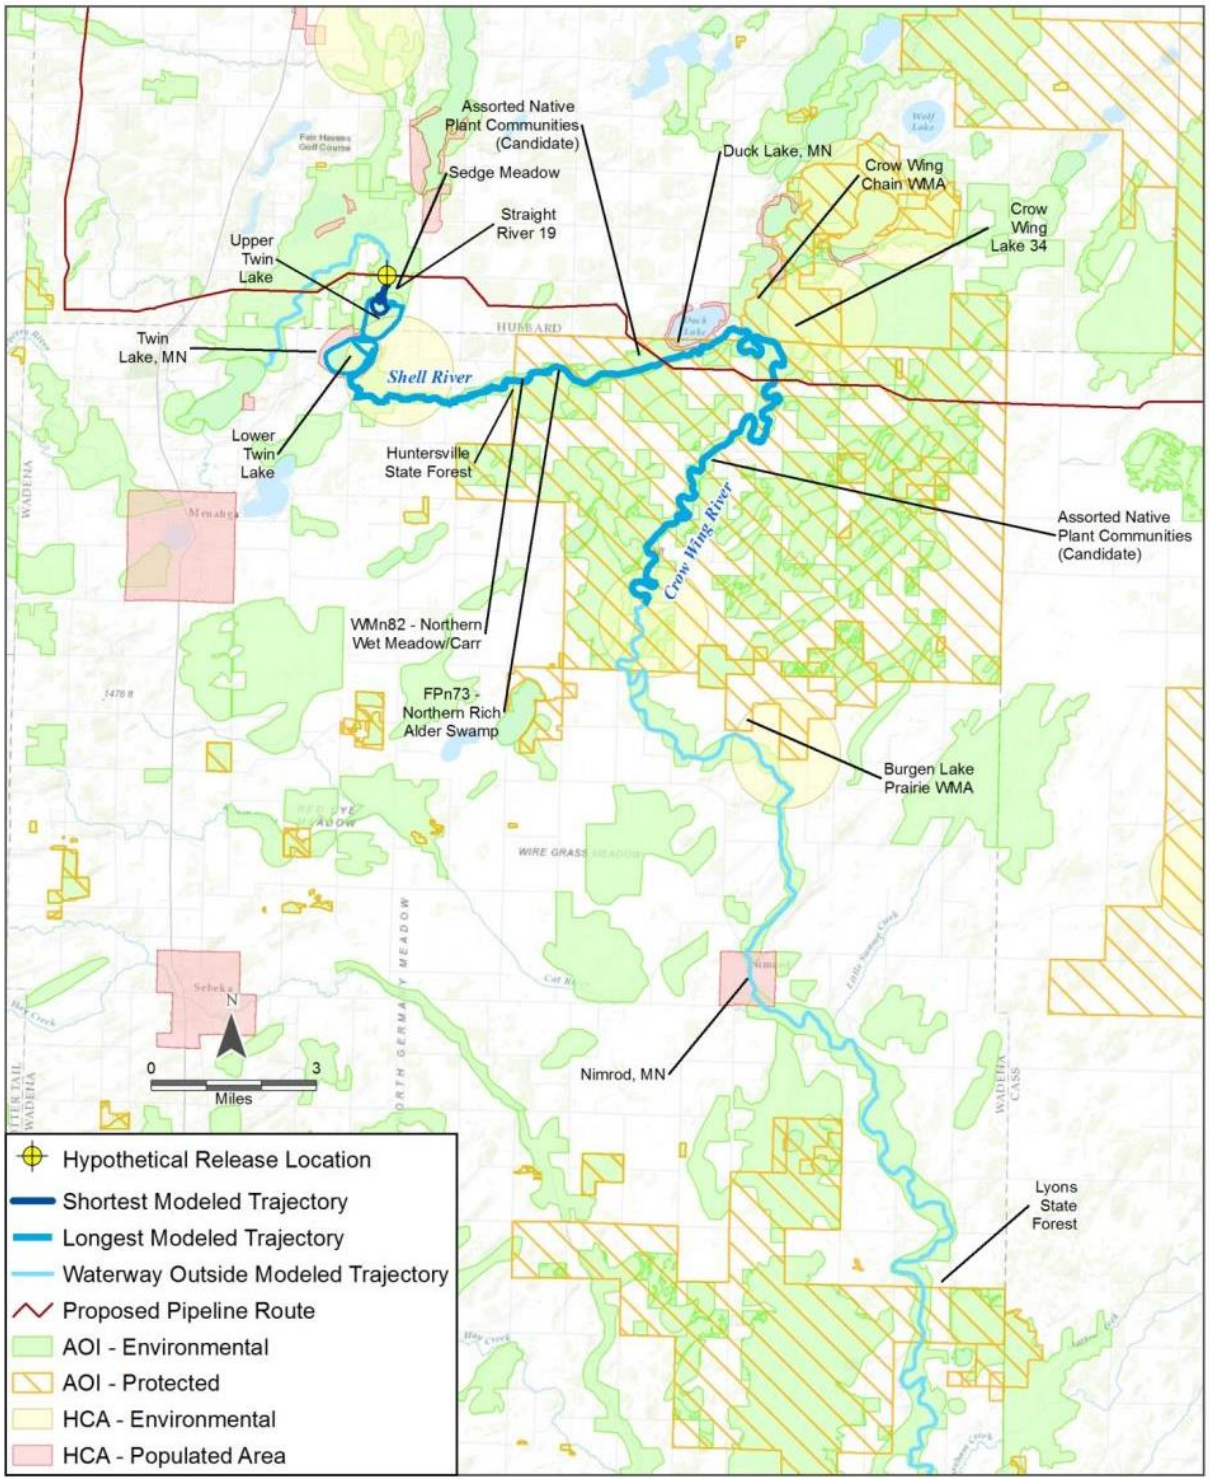

Figure 7-29 HCAs and AOIs Potentially Affected by a Crude Oil Release at the Shell River Crossing Location

Table 7-64 HCAs Potentially Affected by a Release of CLB and Bakken Crude Oil at the Shell River Crossing Location

HCA Type	HCA Subtype	Description / Locations
Environmentally Sensitive Area	N/A	N/A
Population Area	Other	Twin Lake, MN (i.e., Lower Twin Lake) Duck Lake, MN
NOTE: Data for the HCA analysis were obtained from the United States Department of Transportation: Pipeline and Hazardous Materials Safety Administration (USDOT PHMSA) HCA datasets plus additional HCAs compiled by Enbridge during 2010 and 2013.		

Table 7-65 AOIs Potentially Affected by a Release of CLB and Bakken Crude Oil at the Shell River Crossing Location

AOI Type	AOI Subtype	Description / Locations
Environmental	Lake of Biological Significance	Upper Twin Lake
	Wild Rice Lake	Lower Twin Lake Upper Twin Lake
	Native Plant Community (Candidate)	Sedge Meadow. Forests along Crow Wing River, Lowlands/forest along the Shell River, Northern Rich Alder Swamp, Northern Terrace Forest, Northern Wet Meadow/Carr, Upland aspen, wet meadow along river, Wet meadow along river; upland aspen/conifers
	Site of Biodiversity Significance	Crow Wing Lake 34, Straight River 19
Protected Area	State Forest	Huntersville State Forest
	Wildlife Management Area	Crow Wing Chain WMA
NOTE: Data for the AOI analysis were derived from multiple datasets provided on the Minnesota Geospatial Commons website, USGS Protected Areas Database of the United States and the Minnesota Department of Transportation.		

7.5.3 Selection of Key Ecological and Human Environment Receptors for Shell River at Twin Lakes

Taking into account environmental characteristics of the Shell River at Twin Lakes, the potential interactions of released crude oil with key ecological and human environment receptors were screened to identify key receptors for the subsequent environmental effects analysis. The rationale and results of this screening step are provided in Table 7-66.

Table 7-66 Key Ecological and Human Environment Receptors for Shell River at Twin Lakes

Receptor	Relevance for Inclusion as an Environmental Receptor for the Shell River at Twin Lakes Scenario	Selected (Y/N)
Terrestrial Receptors		
Soils	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with no holdup of oil on land. Any oil that contacted soil would be physically remediated to established standards.	N
Groundwater	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with no holdup of oil on land. In the event of an actual oil release, effects on groundwater quality would be localized and/or negligible.	N
Terrestrial Vegetation	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with no holdup of oil on land. Any oil that reaches soil would be physically remediated and vegetative cover would be restored as part of the clean-up process.	N
Aquatic Receptors		
Rivers (Shell River and Crow Wing River)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River with subsequent physical transport downriver of floating oil.	Y
Lakes (Upper and Lower Twin Lake)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River with subsequent physical transport into the Twin Lakes system.	Y
Sediment	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with subsequent physical transport downriver. This allows potential interaction and/or deposition of crude oil residues to sediments.	Y
Shoreline and Riparian Areas	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with subsequent physical transport downriver. This allows potential interaction with shoreline and riparian habitat.	Y
Wetlands	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with subsequent physical transport downriver and potential interaction with wetlands along the river and lakes.	Y
Aquatic Plants	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Shell River upstream of Upper Twin Lake with subsequent physical transport downriver and potential interaction with plants. Aquatic plants are present in Shell River, the Twin Lakes and Crow Wing River as well as associated riparian and wetland habitats.	Y

Table 7-66 Key Ecological and Human Environment Receptors for Shell River at Twin Lakes

Receptor	Relevance for Inclusion as an Environmental Receptor for the Shell River at Twin Lakes Scenario	Selected (Y/N)
Benthic Invertebrates	High. The Shell River and Twin Lake system supports benthic invertebrate communities.	Y
Fish	High. The Shell River and Twin Lake system support fish communities.	Y
Semi-Aquatic Wildlife Receptors		
Amphibians and Reptiles	High. The Shell River and Twin Lake system supports aquatic and semi-aquatic amphibians and reptiles.	Y
Birds	High. The Shell River and Twin Lake system supports waterfowl and other semi-aquatic birds.	Y
Semi-aquatic Mammals	High. The Shell River and Twin Lake system supports semi-aquatic mammals.	Y
Human and Socio-Economic Receptors		
Air Quality	High. The community of Hubbard is located approximately 1.4 miles northeast of the hypothetical release location. The Twin Lakes and Duck Lake are ringed with homes and cottages, and are located along the downstream flow path for released crude oil. Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns.	Y
Human Receptors	High. The Twin Lakes are bordered by homes and used for boating, fishing, and potentially harvesting of wild rice. The Shell and Crow Wing rivers are used recreationally (e.g., hunting, fishing, and canoeing). Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health.	Y
Public Use of Natural Resources	High. The Shell River, Twin Lakes and Crow River are bordered by homes and used for many recreational activities (e.g., hunting, fishing, boating, canoeing). Effects on air quality, water quality, or the presence of crude oil residues in rivers, lakes and riparian habitat could potentially disrupt public use of natural resources (e.g., drinking water supplies).	Y

7.5.4 Modeled Conditions at the Release Location

A description of key modeling assumptions for the environmental effects analysis for the Shell River at Twin Lakes is provided in this section. The OILMAP Land software was used by RPS ASA to simulate hypothetical releases of CLB and Bakken crude oils into the Shell River for a 24 hour period (Chapter 5). A longer time period was not modeled as it was assumed that emergency response measures to prevent further downstream transport of released oil would be in place within the 24 hour period. While OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column (Chapter 5.0). No overland transport

of released CLB or Bakken crude oil was modelled for this hypothetical release location, as it was assumed that released oil would directly enter the watercourse (Chapter 3.0). This is a worst-case assumption for a release of crude oil near the watercourse.

The two crude oil types provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (CLB/CLWB, heavy diluted bitumen crude oil types having higher viscosity and density). The environmental fate of most light, medium or heavy crude oil types that might be transported by the proposed pipeline would lie within the envelope represented by these simulations. Seasonal variations in river flow velocity, temperature, wind speed, and snow and ice cover were all considered at the release location. A summary of key variables is provided in Table 7-67.

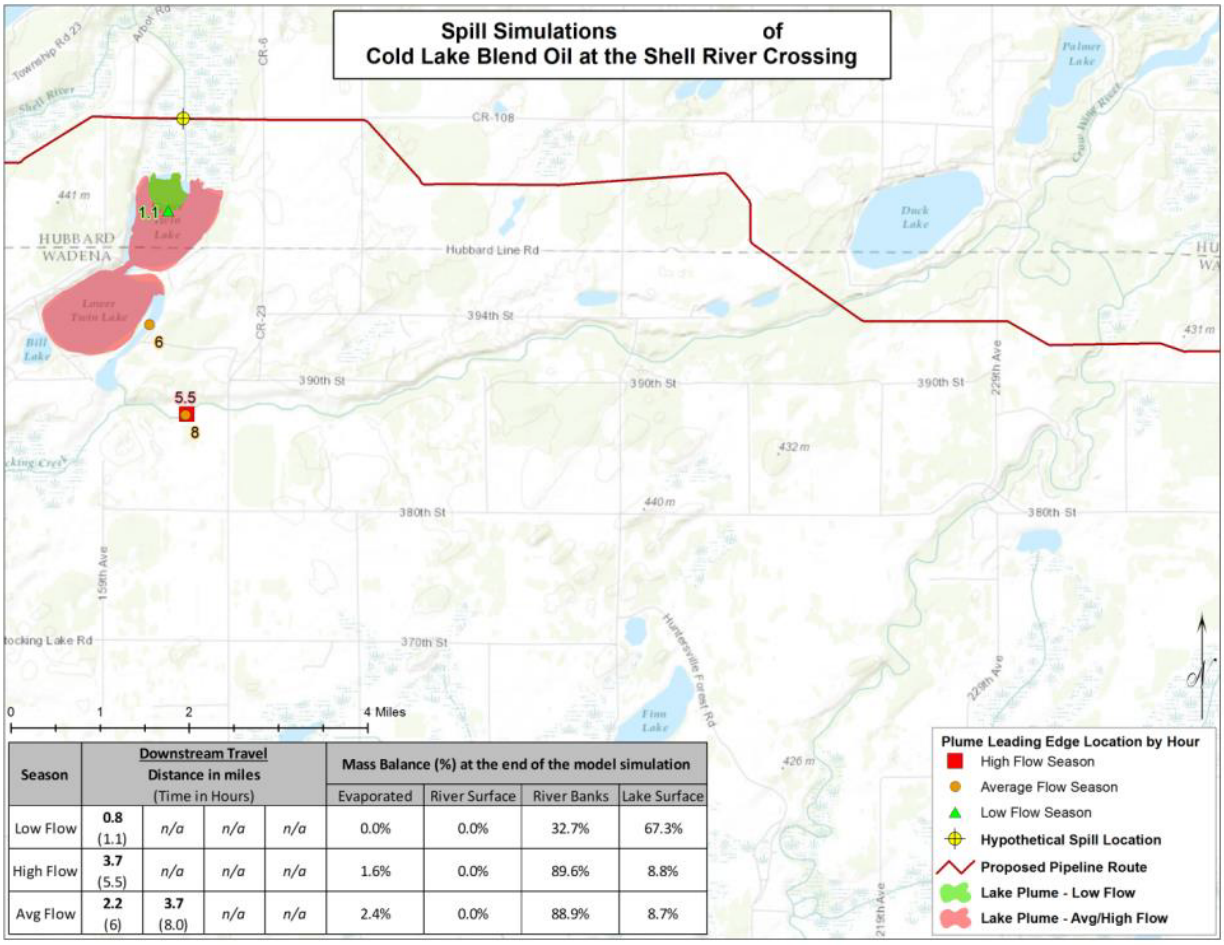
In the event of an actual release, the downstream extents of CLB and Bakken crude oil may be more similar, and the effects of CLB may extend farther downstream than predicted, with patchy coverage.

Table 7-67 Environmental and Hydrodynamic Conditions for the Three Modeled Periods at the Shell River Crossing

Season	Month	Air Temperature (°C)	Wind Speed (m/s)	Average River Velocity (m/s)
Low Flow (Winter)	March	-4.65	4.58	0.25
Average Flow (Summer/Fall)	August	18.61	3.52	0.35
High Flow (Spring)	April	4.04	5.05	0.54
NOTE: A velocity of 1 m/s is equivalent to 2.25 miles per hour.				

The highest average flow velocity of the Shell River coincides with the spring freshet (i.e., April-June), a result of rising temperatures and snowmelt. Average flow would typically occur in summer and fall seasons. August, the month with the warmest temperature was selected to represent the maximum amount of evaporation. The lowest flow velocity occurs in winter (i.e., January–March), and was typified by freezing conditions and probable ice cover on water.

The crude oil release volume was calculated as a full bore rupture, with a maximum time to response in the pipeline Control Center of 10 minutes, followed by a 3-minute period to allow for valve closure. Therefore, the release volume represents the volume of oil actively discharged in the period of time required to detect and respond to the event (taking into consideration the pipeline diameter, pipeline shutdown time, pipeline design flow velocity), followed by the volume of oil lost due to drain-down of the elevated segments of pipeline. The maximum 13-minute response time to valve closure is an Enbridge standard for safe operations and leak detection. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown and full valve closure in the affected pipeline section. While



13 minutes is the maximum time for valve closure, this is a conservative assumption, since a response through to valve closure is expected to occur in less than 13 minutes in a full bore rupture leak scenario. Based on these assumptions, the site-specific hypothetical release volume was estimated of Bakken, CLB or CLWB crude oil.
[NONPUBLIC DATA HAS BEEN EXCISED]

7.5.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils

A summary of the predicted downstream trajectories and mass balance for Cold Lake and Bakken crude oils, under the three seasonal scenarios, is provided in Figure 7-30 and Figure 7-31, respectively. These simulations are assumed to provide bounding conditions for a release of heavy or light crude oil types. The fate of most types of crude oil, if released, would lie within the envelope of predictions for the Cold Lake and Bakken crude oil types. The Cold Lake crude oil was assumed to be CLB for the high flow and average flow scenarios, and to be CLWB for the low flow (winter) scenario. As noted in Chapter 5.0, while OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column.

The maximum simulation duration using OILMAP Land was 24 hours, as it was assumed that emergency response measures to prevent or reduce further downstream transport of released oil would be in place within that length of time. Symbols on the drawings indicate the predicted trajectory during river seasonal flow condition (high corresponding to spring freshet, average corresponding to summer-fall conditions, and low corresponding to winter flow under ice). Numbers associated with the symbols indicate the predicted location of the leading edge of the released oil in the river after 6, 12, 18 or 24 hours. Numbers other than these (e.g., 5.5) indicate the time in hours of the predicted termination of downstream transport of the released oil due to adhesion or holdup of the oil along the river banks. Tables inserted within the Figures also provide information on the mass balance (i.e., oil remaining on the surface of the river, adhering to river banks, or evaporated to the atmosphere) of the released oil at relevant points in time after the start of the release.

Figure 7-31 Predicted Downstream Transport of Bakken Crude Oil at the Shell River Crossing Location

7.5.5.1 Shell River at Twin Lakes Release During High Flow (Spring) Period

Under the high flow scenario, CLB was predicted to travel approximately 3.7 miles downstream within 5.5 hours of the release (Figure 7-23). Under this scenario, CLB was predicted to be transported down the Shell River to the Twin Lakes, and then spread, covering the surfaces of both Upper and Lower Twin Lakes, a total of 0.75 square miles to a thickness of 0.004 inches. In addition, the release is predicted to continue another 1.8 miles down the Shell River below Lower Twin Lake. Approximately 89.6% of the CLB was predicted to oil shorelines, 8.8% to spread over the surface of Upper and Lower Twin Lakes, and 1.6% to have evaporated into the atmosphere.

Bakken crude oil was predicted to be transported approximately 21.9 miles downstream, over the 24-hour modeled period. The Bakken crude oil was predicted to be transported down the

Shell River, and then spread, covering the surfaces of both Upper and Lower Twin Lakes to a thickness of 0.00004 inches. The released oil was then predicted to continue another 20 miles down the Shell River and enter the Crow Wing River. Approximately 46.5% of the Bakken crude oil was predicted to oil shorelines, less than 0.1% to have spread over the surface of Upper and Lower Twin Lakes, 39.4% to have evaporated into the atmosphere, and 14.1% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude oil on the river surface would continue downstream, weathering and oiling shorelines until all the oil was removed from the water surface.

The release of Bakken crude oil under high flow conditions was predicted to result in oiling farther downstream than the CLB. The difference in the extent of downstream transport was primarily the result of differences in the shoreline and lake surface oil retention, and evaporation, between the two oil types. Both oil types were predicted to cover the surface of the Twin Lakes with a crude oil slick, but the Bakken would result in a thinner slick. The Bakken crude oil would also be deposited onto shoreline and riparian areas as a thinner layer of oil than the more viscous CLB crude oil. This result is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline up to that point was oiled to its maximum holding capacity for that oil type) as oil made its way downstream, and the assumption that oil would spread evenly within lake.

A larger proportion of the Bakken crude oil was predicted to evaporate to the atmosphere than was predicted for the CLB. This was due in part to the lighter and more volatile character of the Bakken crude oil. In addition, the greater downstream transport of the Bakken crude oil took more time, and resulted in more water surface area with oil, both of which could allow more of the released oil to evaporate. Volatile components of the CLB would continue to evaporate after becoming stranded on shoreline, but this process was not included within the OILMAP Land model for stranded oil.

7.5.5.2 Shell River at Twin Lakes Release During Average Flow (Summer-Fall) Period

Under average river flow conditions, the CLB crude oil was predicted to travel approximately 3.7 miles downstream within 8 hours of release (Figure 7-30). The CLB crude oil was predicted to be transported down the Shell River and then spread over the surfaces of both Upper and Lower Twin Lakes, a total area of 0.75 square miles to a thickness of 0.004 inches. From here the released oil is predicted to continue another 1.8 miles down the Shell River. Approximately 88.9% of the CLB crude oil was predicted to adhere to shorelines of Shell River, 8.7% to have spread over the surface of Upper and Lower Twin Lake, and 2.4% to have evaporated into the atmosphere.

Relative to the high flow condition, slightly more of the CLB crude oil was predicted to evaporate. This was mainly due to the longer time required for the CLB crude oil to move downstream due to the lower stream velocities. As a result, modeling predicted that slightly less oil might remain on the river shoreline and lake surface under the average river flow condition, as compared to the high flow condition.

Under the average flow condition, Bakken crude oil was predicted to be transported approximately 13.9 miles downstream, over the 24-hour modeled period (Figure 7-24). The Bakken crude was predicted to be transported down the Shell River and then to spread over the surfaces of both Upper and Lower Twin Lakes to a thickness of 0.00004 inches. The released oil was then predicted to continue another 12.0 miles down the Shell and Crow Wing rivers. Approximately 34.7% of the Bakken crude oil was predicted to adhere to shorelines, less than 0.1% to spread over the surface of Upper and Lower Twin Lakes, 42.9% to evaporate to the atmosphere, and 22.4% to remain on the river surface at the end of the 24 hour simulation. It was assumed that emergency response measures to prevent further possible downstream transport of surface oil would be in place within 24 hours of the release.

When compared to the CLB crude oil under average river flow conditions, Bakken crude oil was predicted to be transported farther downstream within 24 hours. It was also predicted that 22.4% of the Bakken crude oil could remain on the river surface at the end of the simulation. The Bakken crude oil was predicted to travel farther downstream than the more viscous and adhesive CLB. Although not modeled here, it is expected that a medium crude oil would exhibit fate and transport properties intermediate between those of the Bakken and CLB crude oil types, with a tendency to behave more like the Bakken crude oil. This is because the viscosity and adhesiveness properties of a medium crude oil would typically be higher and, therefore, more similar to those of the Bakken crude oil, than to the CLB.

7.5.5.3 Shell River at Twin Lakes Release During Low Flow (Winter) Period

Under low flow winter conditions, it was assumed that Shell River and Twin Lakes would be completely frozen over. It was also assumed that CLWB would be released directly into the river from the pipeline under the river bottom, and remained trapped under the ice. The ice cover would limit evaporation of crude oil vapors to the atmosphere.

Under low river flow conditions, CLWB was predicted to be transported a total of 0.8 miles downstream, within 1.1 hours of the release. The CLWB crude oil was predicted to be transported down the Shell River for 0.6 miles, and then spread under the ice of Upper Twin Lake to a thickness of 0.42 inches. The oil was predicted to spread under the ice covering an area of 0.054 square miles of Upper Twin Lake. Approximately 32.7% of the CLWB crude oil was predicted to oil shorelines of Shell River, with the remaining 67.3% spreading under the ice within the lake.

Bakken crude oil was predicted to be transported a total of 1.5 miles downstream within 1.1 hours of the release. The Bakken crude oil was predicted to be transported down the Shell River, and then spread under the ice of Upper Twin Lake to a thickness of 0.075 in. The oil was predicted to spread under the ice covering an area of 0.42 square miles including all of Upper Twin Lake and a portion of Lower Twin Lake. Approximately 30.9% of the CLWB was predicted to oil the shorelines of Shell River, and the remaining 69.1% to spread under the ice within the lake. This would provide only temporary storage of the oil, and oil would be predicted to re-mobilize in response to changes in flow velocity, and particularly during the spring breakup of ice. With the

CLWB below the ice of the river, evaporation of oil to the atmosphere would be negligible in the short-term.

When compared to the CLWB crude oil under low river flow conditions, less of the Bakken crude oil was predicted to accumulate at the river margins under the ice. This was due to the differences in shoreline oil retention between the two oils (i.e., lower viscosity and adhesion of the Bakken crude oil). For this reason the Bakken crude oil was also predicted to have greater mobility under the ice in winter.

7.5.6 Qualitative EHHRA for the Shell River at Twin Lakes

In this section the likely environmental effects of a crude oil release at the pipeline crossing location on the Shell River are described. A worst case crude oil release from a main-line pipeline, such as described here, would be an unlikely event (Chapter 4.0). The proposed pipeline would carry a variety of crude oil types, ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB). Therefore, the following discussion describes the likely environmental effects of a crude oil release on relevant ecological and human environment receptors (identified in Section 7.4.3), using the predicted geographic extent of effects of released Bakken or CLB crude oil types over the 24 hour simulations as bounding conditions. Effects of season (including temperature, river flow conditions, and receptor presence/absence and sensitivity) were also considered in the analysis, as appropriate. The rationale supporting the effects analysis, based on case studies describing the effects of crude oil releases on the various ecological and human environment receptors, was provided in Section 7.1 and Table 7-66.

7.5.6.1 Terrestrial Receptors

For this modeling scenario, the hypothetical release of crude oil is assumed to enter the Shell River with no overland flow. Therefore, environmental effects on soils, terrestrial vegetation and groundwater quality, if any, are assumed to be localized, limited in spatial extent, and readily remediated using conventional clean-up techniques. The environmental effects of a crude oil release on land cover receptors is not considered further for the Shell River at Twin Lakes scenario.

7.5.6.2 Aquatic Receptors

The aquatic environmental and ecological receptors that are most closely associated with the Shell River at Twin Lakes scenario, namely the Shell River, Upper and Lower Twin lakes, and the Crow Wing River, are addressed in this section. These receptors include water and sediment quality in rivers and lakes, shoreline and riparian habitat, wetlands, aquatic plants, benthic invertebrates, and fish.

Crude oil released into the Shell River during the spring (high flow) or summer-fall (average flow) seasons is predicted to travel downstream, interacting with vegetation and seasonal shoreline

areas upstream of the Twin Lakes. Regardless of crude oil type, the OILMAP Land simulations indicate that crude oil would enter and spread to covers the surface of both Upper and Lower Twin lakes. Heavier crude oils would result in thicker oil slicks on the lakes than lighter crude oils. The OILMAP Land simulations (based on a 24 hour model run) indicate that the heavy crude oil could be carried approximately 1.75 miles downstream from the outlet of Lower Twin Lake (Figure 7-4-6). Much greater transport distances are possible for the light crude oil (Figure 7-24). For heavy oil, stranding on shore would be the primary fate, with only small amounts of evaporative weathering of the oil occurring within the first 24 hour period. For light oil, stranding would remain the primary fate, but considerably more of the released oil would be lost to evaporation, and the residual oil would have greater potential mobility of not contained by emergency response measures.

The effects of a crude oil release on benthic invertebrates and fish depend on the characteristics of the released oil and environmental conditions at the time of the release. Acute toxicity to fish is commonly but not always observed in association with crude oil releases, and is an indicator that, at least briefly, concentrations of dissolved hydrocarbons (particularly mono-aromatic hydrocarbons, some low molecular weight PAHs, and short-chain aliphatic hydrocarbons) are sufficiently high to cause acute toxicity due to narcosis. The large volume of water flow associated with the spring freshet may dilute and limit the maximum dissolved hydrocarbon concentration in the Shell River, as compared to periods of lower water flow in summer or winter. Under spring and summer-fall conditions, the spreading of the released oil onto the surface of the Twin Lakes would also provide a large surface area, which would promote the rapid evaporation of volatile (and potentially water soluble) hydrocarbon constituents from the crude oil. It is likely that this would limit effects to fish within the Twin Lakes. As a result, narcotic effects on fish and benthic invertebrates are likely to occur in the Shell River upstream of the Twin Lakes during the spring and summer-fall season, but unlikely to occur in the Twin Lakes as a result of dilution, generally low water turbulence, and rapid evaporation of volatile hydrocarbons from the lake surfaces. As a result, the potential for acute toxicity to fish and benthic invertebrates could be greater for the light oil than for heavier oils.

There would also be high potential for chronic effects of released crude oil on fish eggs and embryos (i.e., induction of deformities or mortality collectively termed blue sac disease). Many of the fish species present in the Shell River and Twin Lakes, including northern pike (for which spawning habitat is abundant in Lower Twin Lake; MN PCA 2014), spawn in the spring and early summer. The eggs and embryos of these species could be exposed to total PAH concentrations in the river and lake water that could be sufficiently high to induce deformities or cause mortality. In addition the potential for phototoxicity, caused by an interaction of UV light with PAHs accumulated in fish tissues, would be greatest for a crude oil release in summer due to high light intensity and long day length. Small fish that are lightly pigmented or transparent (i.e., embryos, larval and juvenile fish) are most susceptible to phototoxicity. The risk of phototoxicity would be partially mitigated by high concentrations of dissolved organic carbon present in the water of the Shell River and Twin Lakes, which would strongly absorb and limit the penetration of UV light into the water column.

Entrainment of small crude oil droplets in the water column during the spring freshet also enhances the potential for light crude oils to interact with suspended sediment particles in the water column resulting in the formation of OPAs. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water such as sediments near the inflows to Upper and Lower Twin lakes, as well as slowly moving areas and backwaters within the Shell River and Crow Wing River system. Formation of true oil-particle aggregates is less likely to occur with heavy crude oils such as diluted bitumen, as the higher viscosity of the oil precludes the ready formation of fine droplets in the water column (Zhou et al. 2015). However, heavy oils can still contact sediment particles along the shoreline, and some accumulation of both light and heavy oils in depositional areas is likely, although the precise mechanisms of deposition may vary. Neither crude oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. During the spring, while heavy crude oil is not predicted on the water surface beyond 3.7 miles downstream of the release within the first 24 hours of the predicted release, it is possible that oil accumulated in depositional areas could mobilize over time and move farther downstream in the Shell River.

The Shell River and Upper and Lower Twin lakes support a wide range of emergent, floating and submerged aquatic plants (Perleberg 2005). Where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Submerged aquatic plants would be less vulnerable, as they would be exposed primarily to dissolved hydrocarbons, and are not considered likely to be among the most sensitive groups of aquatic biota to such exposure. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem could be oiled). Wild rice is an emergent aquatic plant of biological and cultural importance in Minnesota and is abundant within the Twin Lakes. Perleberg reported in 2005 that wild rice was the most common emergent plant species in the Twin Lakes, being more abundant in Lower Twin Lake than Upper Twin Lake, and found from the shoreline to water depths of between 6 and 9 ft. Wild rice provides a food source and nesting cover for many birds, and is also harvested as a food source by people in the area. For a hypothetical release under spring freshet conditions, it is likely that most aquatic plants would still be dormant or submerged, and that environmental effects on this receptor type would be minimal. However, flooded riparian areas and wetland habitats would also be exposed to the released oil, and if not properly remediated, crude oil residues could kill plants in these areas. This could affect the biological integrity and productivity of the habitat, and potentially lead to erosion and further damage to the habitat. In the early summer, oiling of emerging wild rice plants could lead to growth inhibition or death. Later in the summer, oiling at water level of the stems of emerged plants is unlikely to affect the plants. A release of crude oil in winter would have little direct effect on aquatic plants, as they would be in a dormant state.

Crude oil released during the winter (low flow) period could potentially pool on the frozen river surface. If the release was to occur directly to the river below the ice (as is assumed in the OILMAP Land model), or if there were openings in the ice that the released oil could penetrate, the oil could travel downstream under the ice, accumulating in the narrow gap between the ice and the river sediment, or accumulating in hollows under the ice as it moved. Results

provided in Section 7.4.5.3 provide bounding cases for the products likely to be carried in the pipeline. The OILMAP Land simulations indicate that light and heavy crude oil would be transported downstream from the release location, entering and spreading under the ice of the Twin Lakes over the 24 hour model run. Heavy crude oil was predicted to spread under 0.054 square miles of ice in Upper Twin Lake, to a thickness of 0.42 in. Light crude was predicted to spread under the ice of all of Upper Twin Lake and a portion of Lower Twin Lake, covering an area of 0.42 square miles to an average thickness of 0.075 in. For both oil types, the winter ice would effectively inhibit evaporation. This would provide greater potential for dissolution of relatively water soluble crude oil constituents into the water column during the period of lowest dilution flow. Also, both oil types would be predominantly trapped under the ice, remaining mobile at the interface between the lake water and the underside of the ice. Therefore, a release in winter could cause mortality to fish, due to narcosis. This result would be more likely for the light crude oil, which would spread out over a larger area, facilitating release of more water soluble constituents. The heavy crude oil would tend to remain in thicker localized accumulations, and rapid release of more water soluble constituents from a thick layer of crude oil is unlikely. Fish eggs and larvae would generally not be present during the winter, so effects on these life stages due to blue sac disease are not likely, although crude oil residues in water and sediment could, if not adequately remediated, affect fish eggs and larvae in the following spawning season. Phototoxicity is not likely to occur following a release of crude oil in winter due to short day length and lower light intensity in winter, reflection and absorbance of light by snow and ice cover on the lake, and absorbance of UV light by DOC in the water beneath the ice.

Both crude oil types could be accumulated in sediment after a release in winter, and both crude oil types would be subject to re-mobilization with spring breakup of the ice, and increasing water flow rates.

7.5.6.3 Semi-Aquatic Wildlife Receptors

Habitat of the Shell River and Upper and Lower Twin Lake area supports amphibians (e.g., frogs, salamander), reptiles (e.g., turtles, snakes), birds (e.g., ducks, geese, shorebirds, raptors and semi-aquatic mammals (e.g., muskrat, beaver, mink and otter). Details on predicted environmental effects for amphibians and reptiles, birds and mammals are provided below.

7.5.6.3.1 Amphibians and Reptiles

Crude oil released to the Shell River during the spring (high flow) and summer-fall (average flow) periods is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas as it then enters and covers the surfaces of both Upper and Lower Twin Lakes. Heavier crude oils could result in lake plumes with a greater thickness than predicted for lighter crude oils (i.e., 0.004 in. vs 0.00004 in.). The OILMAP Land simulations indicate that crude oil could be carried between 3.7 and 21.9 miles downstream from the point of release, with the extent of downstream transport being in large measure a function of seasonal water flow rate as well as oil viscosity, adhesiveness, and its interactions with shoreline or riparian habitat.

Within the oil-exposed habitats along the lakes and rivers that support amphibians (adults, juveniles, and eggs), oiling effects including mortality would be observed. Turtles appear to be relatively tolerant of external crude oil exposure, and although these animals are likely to become oiled, mortality of turtles as a result of this exposure is less likely. Reptiles like lizards and snakes are primarily terrestrial species and have little or no association with aquatic environments. As a result, exposure of these animals to released crude oils would be limited, albeit likely greater during possible flooding of riparian areas. After the Kalamazoo River oil release in 2010 snakes did not appear to be highly exposed to released oil. A release of light crude oil during the spring would likely have a greater effect than in summer due to the greater predicted downstream transport distance and interaction with more riparian and wetland habitats than later in the year, with the river at lower flow stages.

Amphibians and reptiles undergo a winter dormancy period when temperatures drop below approximately 41 to 45°F. At this time, amphibians and turtles typically bury themselves in river bottom substrates or other similar habitats. Therefore, during the winter (and likely up until April or May when winter ice is gone), these organisms would have very little exposure to released oil moving on the water surface or within the water column.

7.5.6.3.2 Birds

Aquatic and semi-aquatic birds are those that use rivers, lakes, wetlands, and riparian areas as components of their habitats, particularly for nesting and feeding. These birds belong to a variety of guilds including but not limited to waterfowl, divers, gulls and terns, raptors, shorebirds, waders, and some songbirds. They have a variety of dietary preferences, including piscivory, insectivory, omnivory, and herbivory. If exposed to external oiling, the ability of birds to maintain body temperature may be compromised, leading to death as a result of hypothermia. Even if they survive their initial exposure to crude oil, the exposure may require an increase in metabolic rate to survive. In turn this may compromise other life functions such as reproduction or growth. Birds that survive external oiling may experience toxicological stresses as a result of ingesting crude oil residues while preening or attempting to clean and restore the normal properties and functions of feathers. Birds can also transfer potentially lethal quantities of crude oil residue from their feathers to the external surface of eggs, resulting in death of developing embryos.

Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species which leave their summer (and often breeding) habitat in the fall for wintering areas farther south where they can find open-water habitat. However, some birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available. Timely capture and rehabilitation of oiled birds may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, many migratory birds would be returning to riverine and lacustrine habitats in Minnesota, or migrating through these areas on their way to breeding habitats farther north. With cold water temperatures prevailing, aquatic and semi-aquatic birds contacted by crude oil are likely to die as a result of hypothermia. Waterfowl and other semi-

aquatic birds present in the affected river and lake reach would be most affected. Animals upstream, farther downstream, or occupying other nearby habitats, would likely be unaffected as it is assumed that emergency response measures to prevent further possible downstream transport of oil would be in place within 24 hours of the release.

In addition to the habitat offered by the Shell and Crow Wing rivers and their riparian habitats, which include extensive wetlands, the Twin Lakes represent ideal habitat for a variety of aquatic and semi-aquatic bird species, including both breeding and migratory individuals. Therefore, potential for mortality of a large number (i.e., several hundred) of aquatic and semi-aquatic birds would exist, depending upon the precise circumstances and timing of an accidental crude oil release. However, owing to the tremendous regional habitat resources for these birds, large-scale population-level effects are unlikely.

The environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude. With rising water temperatures, mortality of lightly oiled adult birds due to hypothermia becomes less likely than in the spring, and the temporary presence of large numbers of migrating individuals is unlikely. However, in the early summer, environmental effects could include egg mortality due to transfer of oil from the feathers of lightly oiled adult birds in the nest, or mortality of young birds due to direct oil exposure or the loss of a parent bird. Chronic adverse effects on the health of birds that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while preening, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure. Potential effects on aquatic and semi-aquatic birds in the fall would be similar to those in spring, although a smaller overall length of river habitat would be affected due to lower river flows. It is assumed that the Twin Lakes would both be covered by a crude oil slick, and migrating birds that became oiled would be likely to die as a result of hypothermia.

In the winter months, ice cover on the Shell River, Twin Lakes, and Crow Wing River would strongly limit the opportunities for aquatic and semi-aquatic birds to occupy this habitat. As such, exposure of birds to released crude oil in winter would be very limited.

7.5.6.3.3 Semi-aquatic Mammals

While the semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, this assessment focuses particularly upon species that have a primary association with the aquatic environment, such as muskrat and beaver (herbivores), American mink (carnivore-*piscivore*), and river otter (*piscivore*). These species are at greater risk of exposure to an oil release in water than terrestrial mammals. The area of the Shell and Crow Wing rivers assessed here, which includes the Twin Lakes and extensive riparian wetland areas, provides high-quality habitat for these animals.

Effects to semi-aquatic mammals are typically described in terms of direct physical effects (e.g., hypothermia due to loss of insulation), direct toxicological effects (e.g., gastro-enteropathy caused by ingestion of crude oil residues while grooming oiled fur or ingesting food), and

indirect effects caused by changes to habitat (e.g., land cover and food availability). The spatial extent along the Shell River where effects may occur, and the magnitude of effects, is related to the season and river flow rate, and the type of oil released. Effects to semi-aquatic mammals relate more to the amount of time spent in the water and oil-contaminated riparian habitat (and consequent exposure to physical oiling) than to dietary preferences. Timely capture and rehabilitation of oiled mammals may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, with cold water temperatures prevailing, semi-aquatic mammals contacted by crude oil are likely to die as a result of hypothermia. Based on the OILMAP Land simulations, the potentially affected river reach could range from 3.7 to 21.9 miles in extent, and could include the Twin Lakes. Animals upstream, farther downstream where there is no exposure, or occupying other nearby habitats, would likely be unaffected. Therefore, although mortality of a considerable number of semi-aquatic mammals could be expected, large-scale (i.e., regional) population level effects are unlikely. Environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude than those associated with a release during spring. With rising water temperatures, mortality of lightly oiled semi-aquatic mammals due to hypothermia is expected to be less likely than in the spring. Chronic adverse effects on the health of semi-aquatic mammals that survive their initial exposure to crude oil are possible as a result of ingesting crude oil residues while grooming, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure.

In the winter months, muskrat and beaver are likely to reduce their activity levels, although American mink and river otter would remain active. As such, exposure of semi-aquatic mammals like muskrat and beaver in winter would be lower than expected for mammals like mink and otter. Animals that became oiled in the winter would be likely to rapidly die as a result of hypothermia.

7.5.6.4 Human and Socio-Economic Receptors

Crude oils are complex mixtures of hydrocarbon compounds. Light crude oils typically contain more VOCs than heavier crude oils, although diluted bitumen may contain similar amounts of VOCs to light crude oils, depending upon the type and amount of diluent they contain. Air quality in the vicinity of a crude oil release, and along the downstream corridor, would be affected by the release of VOCs (such as benzene, which is often used as an indicator substance) primarily within the first 24 hours of an oil release.

The communities of Twin Lake and Duck Lake, Minnesota were identified through the HCA analysis as population areas. The OILMAP Land modeling indicated that the leading edge of released heavy oil would pass through Twin Lake, but that downstream transport would be limited to a short reach of the Shell River below Lower Twin Lake. In contrast the leading edge of released light oil is predicted to pass through Twin Lake, and to pass by Duck Lake, under spring

and summer-fall flow conditions. In winter, both types are predicted to remain under ice in the Twin Lakes. Lower Twin Lake has a greater number of structures than Upper Twin Lake, with the majority located on the northwestern and southwestern banks. Duck Lake, which is north of the Shell River and not expected to receive release crude oil, is surrounded by homes and cottages. In addition a number of structures are located along the banks of the Shell River and Crow Wing River, and in the unincorporated community of Huntersville along the Crow Wing.

Typical human health effects associated with short-term (acute) inhalation of volatiles from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term or repeated skin contact with crude oil may result in dermatitis. The case studies (Section 7.1) do not reveal any instances of human fatality as a result of inhalation of crude oil vapor. Similarly, ATSDR (1995) report that there are no known instances of human fatality as a result of inhalation of vapor from fuel oils, which would be comparable to light crude oils.

The potential for VOC inhalation exposures by the public would be greatest near and downwind from the release site and near to the Shell River and Twin Lakes, while the released oil is on the water surface. In the unlikely event of a crude oil release, residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most of the volatile hydrocarbons would be lost within the first 24 hours following a release of crude oil. It is also expected that emergency response personnel would contact such residents and advise them to evacuate. Actual or potential exposure to crude oil vapor may result in residents leaving, or being advised to leave their homes for a period of time while the emergency response takes place.

No drinking water HCAs were identified along the path of the release. However, a number of homes are located along the trajectories of predicted releases and could rely on groundwater as a drinking water source. There are 59 groundwater wells reported in the lower Shell River (downstream of Lower Twin Lake), most of which are used for agricultural irrigation (MN PCA 2014). In the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. Based upon case studies involving crude oil releases elsewhere, this process could take a few days to two weeks, but reports of crude oil releases affecting private wells are rare, making this an unlikely effect.

Relatively little has been published regarding the long-term effects of human exposure to a crude oil release. Health effects observed in residents and clean-up workers in the months following such releases generally do not persist over the long term (Eykelbosh 2014). The International Agency for Research on Cancer (IARC 1989) has determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans. Although toxicological effects from short-term exposure to volatile hydrocarbons are reversible when exposure is reduced, other health effects such as anxiety and depression may occur, and may persist, regardless of whether the individual was physically exposed to hydrocarbons.

Effects of a crude oil release on human receptors would be generally similar for the spring (high flow) and summer-fall (average flow) seasons. In summer, the warmer temperatures and slower river flow velocities in the summer would promote more rapid evaporation of volatile hydrocarbons in a smaller area. The flow modeling suggests that the light crude oil (i.e., Bakken crude oil) is likely to be transported farther downstream within 24 hours than the heavy crude oil (Cold Lake diluted bitumen). However, for either crude oil type, the Twin Lakes represent an area where released crude oil would be expected to spread, and to affect a local population of individuals, before moving downstream as more weathered oil. As a result, a release of the light crude oil could affect a larger number of individuals than a release of the heavy crude oil type, but the difference between the crude oil types is not likely to be large for this hypothetical release example. The individuals most likely to be exposed would be located in the vicinity of the Twin Lakes. Both Bakken crude oil and Cold Lake diluted bitumen are expected to contain similar overall amounts of volatile hydrocarbons, so differences related to the chemical characteristics of the released oil are also likely to be minor.

No overland transport of released crude oil was modelled for this hypothetical release location. Infiltration of crude oil into soil and subsequently into groundwater would be limited. During the spring freshet period, the Shell River is susceptible to flooding and can overtop its banks and spread into the surrounding farmland. A release of light and medium crude oils during this period would provide a potential pathway for oil deposition to soil in low-lying areas. Light and medium crude oils would be expected to become dispersed over a large area, and are readily biodegraded, so that persistent accumulation of these oil types in riparian areas or temporarily flooded farmland is unlikely. Heavy crude oils and diluted bitumen are more likely to be deposited as thicker layers of more persistent oil, and could likely require more active remediation of affected areas.

The Shell River, Twin Lakes, and Crow Wing River provide recreational opportunities (e.g., fishing, hunting, boating, swimming, camping) at many locations downstream of the hypothetical release location. Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. Fisheries regulators and public health officials typically close fisheries until it is confirmed through monitoring that fish consumption is not a threat to public health. This standard approach is an effective mitigation strategy to protect human receptors for contact with constituents in the oil. Under winter conditions the released crude oil is expected to remain in the Twin Lakes.

7.5.6.5 Summary and Conclusions

Expected environmental effects to key ecological and human environment receptors after a hypothetical large crude oil release to the Shell River at Twin Lakes area have been assessed. The proposed pipeline could carry a variety of crude oil types ranging from very light (e.g.,

Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB). The discussion of expected environmental effects on receptors considers these crude oil types as bounding conditions.

Ecosystem components, terrestrial receptors, aquatic receptors, semi-aquatic wildlife receptors, and human and socio-economic receptors were screened to identify those most likely to have interaction with released oil. Selected receptors for qualitative assessment are highlighted in Table 7-66, discussed in detail in Sections 7.5.6.1 to 7.5.6.4, and likely environmental effects are summarized in Table 7-68.

Table 7-68 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Shell River

Receptor	Expected Environmental Effects of Released Crude Oil to the Shell River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Terrestrial Receptors			
Soils	It is assumed in the model that crude oil would enter directly into the Shell River with no holdup of oil on land. In the event of an actual oil release, any oil on land would undergo prompt and effective remediation. Residual effects on plant communities, soil or groundwater quality are unlikely.	SAME	SAME
Groundwater		SAME	SAME
Terrestrial Vegetation		SAME	SAME
Aquatic Receptors			
Rivers (Shell River, Crow Wing River)	Both light and heavy oil would travel downstream from the release location, affecting the Shell River, and in some cases also extending to the Crow Wing River. Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, but would be thinner on the water, and less persistent where they contact shoreline habitat. Both light and heavy crude oils are predicted to travel similar travel distances under winter conditions, although more of the heavy oil would be likely to remain trapped along the edges of the rivers. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column, meaning that potentially toxic fractions of the light oils would more readily dissolve into the water column.	MORE	LESS
Lakes (Upper and Lower Twin Lake)	Both light and heavy oil would travel downstream from the release location, enter, and spread over the surface of the Twin Lakes. Heavier crude oils would result in surface oil slicks that would be thicker than those expected for lighter crude oils. Under winter conditions, oil could form thicker layers under the ice (0.075 to 0.42 inches for light and heavy oil, respectively) and as a consequence would spread to a lesser extent. In winter the CLWB is predicted to remain confined to the northern part of Upper Twin Lake, whereas lighter oil could flow under ice to affect all of Upper Twin Lake and part of Lower Twin Lake.	MORE	LESS

Table 7-68 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Shell River

Receptor	Expected Environmental Effects of Released Crude Oil to the Shell River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Sediment	Lighter crude oils are predicted to travel farther downstream than heavier crude oils in spring and summer-fall conditions, with both oil types travelling similar distances under winter conditions. Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. The low viscosity of the lighter type crude oils could potentially result in a larger amount of oil entrainment as fine droplets as compared to heavier blends, resulting in the formation of OPAs, which could both sink, and enhance biodegradation. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water, particularly the Twin Lakes. Contact between the weathered diluted bitumen and lake shorelines is also likely to result in mixing of mineral particles into the crude oil, which could then be deposited to sediments as aggregates of oil and mineral in larger droplets or globules. If not recovered, these aggregates could move from shoreline areas into deeper water as a result of wave action and resuspension followed by deposition. Low molecular weight aromatic hydrocarbons would also be expected to dissolve into the water column within the Twin Lakes, where they could adsorb onto suspended sediment and organic matter. Under winter conditions, more of the heavy crude oil is predicted to become trapped along the margins of the rivers and lakes, and this oil is also likely to interact with sediment, resulting in mixing of oil and sediment, or formation of oil-particle aggregates. The spring freshet is a major seasonal factor that can flush river sediments leading to restoration of damaged habitat, and dispersal of oil-particle aggregates in a way that enhances natural recovery.	LESS	MORE
Shoreline and Riparian Areas	Both light and heavy oil would travel downstream from the release location. Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, but would be thinner and less persistent where they contacted shorelines and riparian habitat. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. For heavy oil, stranding on shore would be the primary fate. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation. Flooding of riparian and wetland habitats in spring could lead to stranding of crude oils in these habitats, with heavy crude oil likely to be deposited as patties or tar balls, in contrast to light crude oil which would be deposited as a thin layer or sheen.	LESS	MORE

Table 7-68 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Shell River

Receptor	Expected Environmental Effects of Released Crude Oil to the Shell River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Aquatic Plants	The Shell River and Twin Lakes support a wide range of emergent, floating and submerged aquatic plants. Where they occur, floating aquatic plants would be expected to be killed if contacted by a floating oil slick. Submerged aquatic plants would be less vulnerable. Emergent aquatic plants are generally quite tolerant of moderate exposure to floating oil (such that a portion of the stem was oiled). However, given the extent of predicted oiling in the Twin Lakes in spring and summer-fall seasons, death of emergent plants from contact with crude oil, particularly the lighter crude oil type, is also possible.	MORE	LESS
Benthic Invertebrates	Environmental effects on benthic invertebrates would be limited to areas affected by the released oil. In the short-term, the low viscosity of light crude oil would result in greater potential for oil entrainment as fine droplets, as compared to heavier blends. This would enhance dissolution of low molecular weight aliphatic and aromatic hydrocarbons into water (with resulting acute toxicity), in addition to promoting oil-particle interaction and potential deposition of oil to sediment. For heavy crude oil, there would be less potential for dissolution of hydrocarbons into the water, but greater long-term potential for deposition of tar balls and patties as a result of oil interaction with sediment. These could accumulate in depositional areas, resulting in chronic effects on benthic invertebrates.	SAME	SAME
Fish	Environmental effects on fish would be limited to areas affected by the released oil. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column. This would enhance the dissolution of potentially toxic fractions of the light oil into the water column. As a result, the potential for acute toxicity to fish due to narcosis would be greater for the light oil than for heavy oil. Potential chronic effects on fish eggs and embryos (e.g., blue sac disease) could also occur, but would be most likely to occur in spring and early summer, when most species spawn. The potential for phototoxicity, caused by an interaction of ultraviolet light with PAHs accumulated in fish tissues, would be greatest in summer due to high light intensity and long day length.	MORE	LESS

Table 7-68 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Shell River

Receptor	Expected Environmental Effects of Released Crude Oil to the Shell River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Semi-Aquatic Wildlife Receptors			
Amphibians and Reptiles	Environmental effects on amphibians and reptiles would be limited to areas affected by the released oil. Light crude oil is expected to travel farther downstream under spring and summer conditions than heavy crude oil, but would be thinner and less persistent on the water. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. Flooding of riparian habitat in spring could lead to stranding of crude oils in this habitat. Within these habitats, oiling effects on adults, juveniles, and eggs could potentially be observed. Higher potential would exist for effects on amphibians than for turtles, which appear to be somewhat tolerant of external oiling. Dormancy of amphibians and reptiles in winter and early spring means exposure to oil released at this time of year could be negligible, and adverse environmental effects unlikely.	MORE	LESS
Birds	Mortality of oiled aquatic and semi-aquatic birds would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil, so environmental effects could be more spatially extensive for light crude oil types. However, the Twin Lakes provide most of the highest quality habitat for aquatic and semi-aquatic birds along the predicted trajectory of a release, and numbers of birds could be high during periods of migration. As such, oiling of birds in the Twin Lakes would be the primary outcome of a release, independent of oil type. This habitat is affected equally by light and heavy crude oils under spring and summer-fall conditions. Few birds are present in winter, so effects would be minimal in that season.	SAME	SAME
Semi-aquatic Mammals	Mortality of oiled semi-aquatic mammals would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil in all seasons, so environmental effects could be more spatially extensive for light crude oil types. However, the Twin Lakes provide most of the highest quality habitat for semi-aquatic mammals, and this habitat is affected equally by light and heavy crude oils under spring and summer-fall conditions. Adverse effects on mink and otter would be particularly severe in winter, due to the effects of oil in the insulating properties of fur, in combination with cold water temperatures. However, muskrat and beaver might be spared due to their lower activity levels in winter.	MORE	LESS

Table 7-68 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Shell River

Receptor	Expected Environmental Effects of Released Crude Oil to the Shell River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Human and Socio-Economic Receptors			
Air Quality	Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns. Light crude oils typically contain more VOCs than heavier crude oils, although the VOC content of diluted bitumen may be similar to that of light crude oil, depending on the type and quantity of diluent used in its manufacture. Air quality in the vicinity of the oil release would be most affected within the first 24 hours of an oil release. Light crude oil is likely to be transported farther downstream within 24 hours than the heavy crude oil. As a result, environmental effects on air quality could be more spatially extensive for light crude oil types. Under winter conditions, cold temperatures, ice cover and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS
Human Receptors	Typical human health effects associated with short-term inhalation of VOC from crude oil releases include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain; fatality is unlikely. Residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most volatile hydrocarbons would be lost within 24 hours following a release. Light crude oil (Bakken) is likely to be transported farther downstream within 24 hours than the heavy crude oil (Cold Lake diluted bitumen). As a result, a release of the light crude oil may affect a larger number of individuals than a release of the heavy crude oil type. Under winter conditions, cold temperatures, ice cover and absorption of crude oil into snow pack would strongly limit emissions of VOCs, in addition to constraining the area of effects.	MORE	LESS

Table 7-68 Environmental Effects Summary Table for Pipeline Crude Oil Releases to Shell River

Receptor	Expected Environmental Effects of Released Crude Oil to the Shell River	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Public Use of Natural Resources	Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Light crude oil is predicted to be transported farther downstream than heavy crude oil following a release, affecting a larger area and potentially interrupting public use of natural resources over a larger area. No drinking water HCAs were identified along the path of the release. However, a number of homes are located along the trajectory of a predicted release and could rely on groundwater as a drinking water source. In the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. It is unlikely that a crude oil release to the Shell River would result in adverse health effects to consumers of drinking water. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. The Twin Lakes would be the area where public use of natural resources would be most affected by a release of crude oil. While light crudes will spread further over the lakes exposing, disrupting larger areas, the greater persistence of heavy crude oil is likely to affect such use over a longer period of time than would be the case for lighter crude oil types.	MORE	LESS

7.6 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE RED RIVER

The Red River is located along the border of North Dakota and Minnesota, and flows north into Canada. The pipeline crossing is located approximately 3 miles east of Bowesmont, North Dakota and 9 miles southwest of Hallock, Minnesota. This scenario captures a hypothetical release of crude oil to the Red River with downstream transport to the north. From the hypothetical release point, the Red River flows past the communities of Pembina, North Dakota and St. Vincent, Minnesota, before crossing the border with Canada near the town of Emerson, Manitoba. For the purposes of this assessment, environmental effects outside of the jurisdiction of the United States of America are not considered.

At the proposed pipeline crossing location and downstream, the Red River is approximately 150 to 400 ft wide and drops 6 ft in elevation over 35 river miles of flow. The river occupies a well-defined sinuous channel with grassy, forested, and muddy banks nestled between predominantly agricultural lands, although the shorelines are often lined with trees. Flooding of the Red River is common in spring and can be extensive due to the generally flat topography. As identified in Chapter 3.0, the Red River is found in the Red River Prairie ecological subsection of the Prairie Parkland Province in Minnesota.

7.6.1 Description of the Freshwater Environment

The Red River flows north along a well-defined channel through predominantly agricultural lands. The average velocity of the Red River changes with season, with slowest velocities (e.g., about 1.0 mph) expected during low flow periods in the winter, and greater velocities (e.g., about 2.5 mph) during the spring high flow period. During the spring freshet, the Red River is susceptible to flooding and can overtop its banks and spread into surrounding farmland and communities.

Although the Red River is a muddy river, the water quality is high (MN DNR 2014). This is exemplified in August when millions of mayflies rise up from the water in massive hatches (MN DNR 2014). The habitats of the Red River and its tributaries support more than 70 species of fish (MN DNR 2014). The river offers easily accessible fishing opportunities for channel catfish, walleye, northern pike, smallmouth bass, sauger and lake sturgeon (MN DNR 2014). With the exception of lake sturgeon (*Acipenser fulvescens*), most fish species in the Red River are self-sustaining and do not require stocking to maintain healthy populations. The MN DNR began a stocking program to re-establish sturgeon in 1997. Several thousand lake sturgeon have since been released into the Red River basin in the hope that by the time they become sexually mature (15–20 years), dam removal and other naturalization projects will have reconnected the river to historical spawning tributaries (MN DNR 2014).

In addition to the highly valued fishery of the Red River, many bird species (e.g., wood ducks, hooded mergansers, mallard, northern shoveler, blue-winged teal and Canada goose, FWOR 2000) utilize the river and riparian habitat (e.g., oxbows) for feeding, nesting and resting. The Red River Prairie Subsection is home to 83 Species of Greatest Conservation Need (SGCN). These include amphibians (1 species), birds (54 species), fish (2 species), insects (10 species), mammals (9 species), mollusks (3 species), reptiles (3 species) and spiders (1 species) (MN DNR 2006). Of these species, 36 are afforded federal or state endangered, threatened, or of special concern status (MN DNR 2006; MN DNR 2016). It is foreseeable that some of these SGCN could utilize aquatic habitats along the Mississippi River.

Two access points downstream from the proposed pipeline crossing location were visited in September 2016 to provide additional insight into baseline environmental conditions for the Red River. Representative site photographs are provided in Figure 7-32 through Figure 7-35. Field observations are summarized in Table 7-69.

7.6.2 High Consequence Area Assessment for the Red River

As defined in Section 7.0, HCAs include populated areas, drinking water source areas, ecologically sensitive areas, and commercially navigable waterways. Sensitive AOIs include Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks). The principal HCAs include the population centers of Pembina, ND and St. Vincent, MN (Table 7-70). The Red River also flows past recreational areas, protected areas, and environmental AOIs (Table 7-71). These include water access sites and Bureau of Land Management land. The locations of the HCAs and AOI are shown in Figure 7-36.

Table 7-70 High Consequence Areas Potentially Affected by a Release of Cold Lake Blend or Bakken Crude Oil at the Red River Crossing Location

HCA Type	HCA Subtype	Description / Locations
Environmentally Sensitive Area	N/A	N/A
Population Area	Other Population Area	Pembina, ND
	Other Population Area	St. Vincent, MN
NOTE: Data for the HCA analysis were obtained from the United States Department of Transportation: Pipeline and Hazardous Materials Safety Administration (USDOT PHMSA) HCA datasets plus additional HCAs compiled by Enbridge during 2010 and 2013.		

Table 7-71 Areas of Interest Potentially Affected by a Release of Cold Lake Blend or Bakken Crude Oil at the Red River Crossing Location

AOI Type	AOI Subtype	Description / Locations
Recreational	State Land	Water Access Site
Protected Area	Bureau of Land Management	BLM Land
Environmental	US NRCS Easement	Emergency Watershed Protection Program - Floodplain Easement
	Site of Biodiversity Significance	St. Vincent 11
NOTE: Data for the AOI analysis were derived from multiple datasets provided on the Minnesota Geospatial Commons website, USGS Protected Areas Database of the United States and the Minnesota Department of Transportation.

7.6.3 Selection of Key Ecological and Human Environment Receptors for Red River

Taking into account environmental characteristics of the Red River, the potential interactions of released crude oil with key ecological and human environment receptors were screened to identify key receptors for the subsequent environmental effects analysis. The rationale and results of this screening step are provided in Table 7-72.

Table 7-72 Key Ecological and Human Environment Receptors for the Red River

Receptor	Relevance for Inclusion as an Environmental Receptor for the Red River Scenario	Selected (Y/N)
Terrestrial Receptors		
Soils	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with no holdup of oil on land. In the event of an actual oil release, oil remaining on or in the soil would be physically remediated to established standards.	N
Groundwater	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with no holdup of oil on land. In the event of an actual oil release, effects on groundwater quality would be localized and/or negligible.	N
Terrestrial Vegetation	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with no holdup of oil on land. Any oil that reaches soil would be physically remediated and vegetative cover would be restored as part of the cleanup process.	N
Aquatic Receptors		
Rivers (Red River)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with subsequent physical transport downriver.	Y
Lakes	Low. It is possible that under severe flood conditions the Red River could interact with Lake Stella (a small lake approximately 0.5 miles away from the nearest bank of the Red River). However, an assumption made in the fate modeling for this scenario is that released oil would remain in the Red River after a release.	N
Sediment	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with subsequent physical transport downriver. This allows potential interaction and/or deposition of crude oil residues to sediments.	Y
Shoreline and Riparian Areas	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with subsequent physical transport downriver. This allows potential interaction with shoreline and riparian habitat.	Y

Table 7-72 Key Ecological and Human Environment Receptors for the Red River

Receptor	Relevance for Inclusion as an Environmental Receptor for the Red River Scenario	Selected (Y/N)
Wetlands	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Red River with subsequent physical transport downriver. There is negligible to no wetland habitat in the vicinity of the predicted release trajectory.	N
Aquatic Plants	Low. The high suspended sediment load of the Red River limits light penetration and opportunities for the development of a substantial aquatic plant community.	N
Benthic Invertebrates	High. The Red River at supports a diverse benthic invertebrate community.	Y
Fish	High. The Red River supports fish.	Y
Semi-Aquatic Wildlife Receptors		
Amphibians and Reptiles	High. The Red River supports amphibians and reptiles.	Y
Birds	High. The Red River supports a diverse bird community.	Y
Semi-aquatic Mammals	High. The Red River supports semi-aquatic mammals.	Y
Human and Socio-Economic Receptors		
Air Quality	High. The communities of Pembina, ND and St. Vincent, MN are located approximately 30 miles north of the hypothetical release location. Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns.	Y
Human Receptors	High. The communities of Pembina, ND and St. Vincent, MN are located approximately 30 miles north of the hypothetical release location. Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health.	Y
Public Use of Natural Resources	High. The Red River downstream of the crossing is shared by two public water access sites. In addition, Fort Daer Landing and Recreation Area as well as Pembina State Park are also along the trajectory of the modeled release. Effects on air and water quality, or the presence of crude oil residues in the sediment and riparian habitat, could potentially disrupt public use of natural resources (e.g., drinking water, hunting, fishing, recreation).	Y

7.6.4 Modeled Conditions at the Release Location

A description of key modeling assumptions for the environmental effects analysis for the Red River scenario is provided in this section. The OILMAP Land software was used by RPS ASA to simulate hypothetical releases of Cold Lake Blend and Bakken crude oils into the Red River (Chapter 5.0) for a 24 hour period, or until the released crude oil reached the border between the United States and Canada. A longer time period was not modeled as it was assumed that

emergency response measures to prevent farther downstream transport of released oil would be in place within the 24 hour period. While OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column (Chapter 5.0). No overland transport of released Cold Lake Blend or Bakken crude oil was modelled for this hypothetical release location, as it was assumed that released oil would directly enter the watercourse (Chapter 3.0). This is a worst-case assumption for a release of crude oil near the watercourse.

The two crude oil types provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (Cold Lake Blend/Winter Blend, heavy diluted bitumen crude oil types having higher viscosity and density). Seasonal variations in river flow, temperature, wind speed, and snow and ice cover were all considered at the release location. A summary of key variables is provided in Table 7-73.

In the event of an actual release, the downstream extents of CLB and Bakken crude oil may be more similar, and the effects of CLB may extend farther downstream than predicted, with patchy coverage.

Table 7-73 Environmental and Hydrodynamic Conditions for the Three Modeled Periods for the Red River Crossing

Season	Month	Air Temperature (°C)	Wind Speed (m/s)	Average River Velocity (m/s)
Low Flow (Winter)	February	-14.68	5.19	0.31
Average Flow (Summer)	August	19.78	3.98	0.44
High Flow (Spring)	April	4.02	5.05	1.02
NOTE: A velocity of 1 m/s is equivalent to 2.25 miles per hour.				

The highest average flow velocity of the Red River coincides with the spring freshet (i.e., April-June), a result of rising temperatures and snowmelt. Average flow would typically occur during summer and fall seasons. August, the month with the warmest temperature, was selected to represent the maximum amount of evaporation. The lowest flow rate occurs in winter (i.e., February), and was typified by freezing conditions and probable ice cover on water.

The crude oil release volume was calculated as a full bore rupture, with a maximum time to response in the pipeline Control Center of 10 minutes, followed by a 3-minute period to allow for valve closure. The release volume therefore represents the volume of oil actively discharged in the period of time required to detect and respond to the event (taking into consideration the pipeline diameter, pipeline shutdown time, pipeline design flow velocity), followed by the volume of oil lost due to drain-down of the elevated segments of pipeline. The maximum

13-minute response time to valve closure is an Enbridge standard for safe operations and leak detection. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown and full valve closure in the affected pipeline section. While 13 minutes is the maximum time for valve closure, this is a conservative assumption, since a response through to valve closure is expected to occur in less than 13 minutes in a full bore rupture leak scenario. Based on these assumptions, the site-specific hypothetical release volume was estimated Bakken, CLSB, or CLWB crude oil.

[NONPUBLIC DATA HAS BEEN EXCISED]

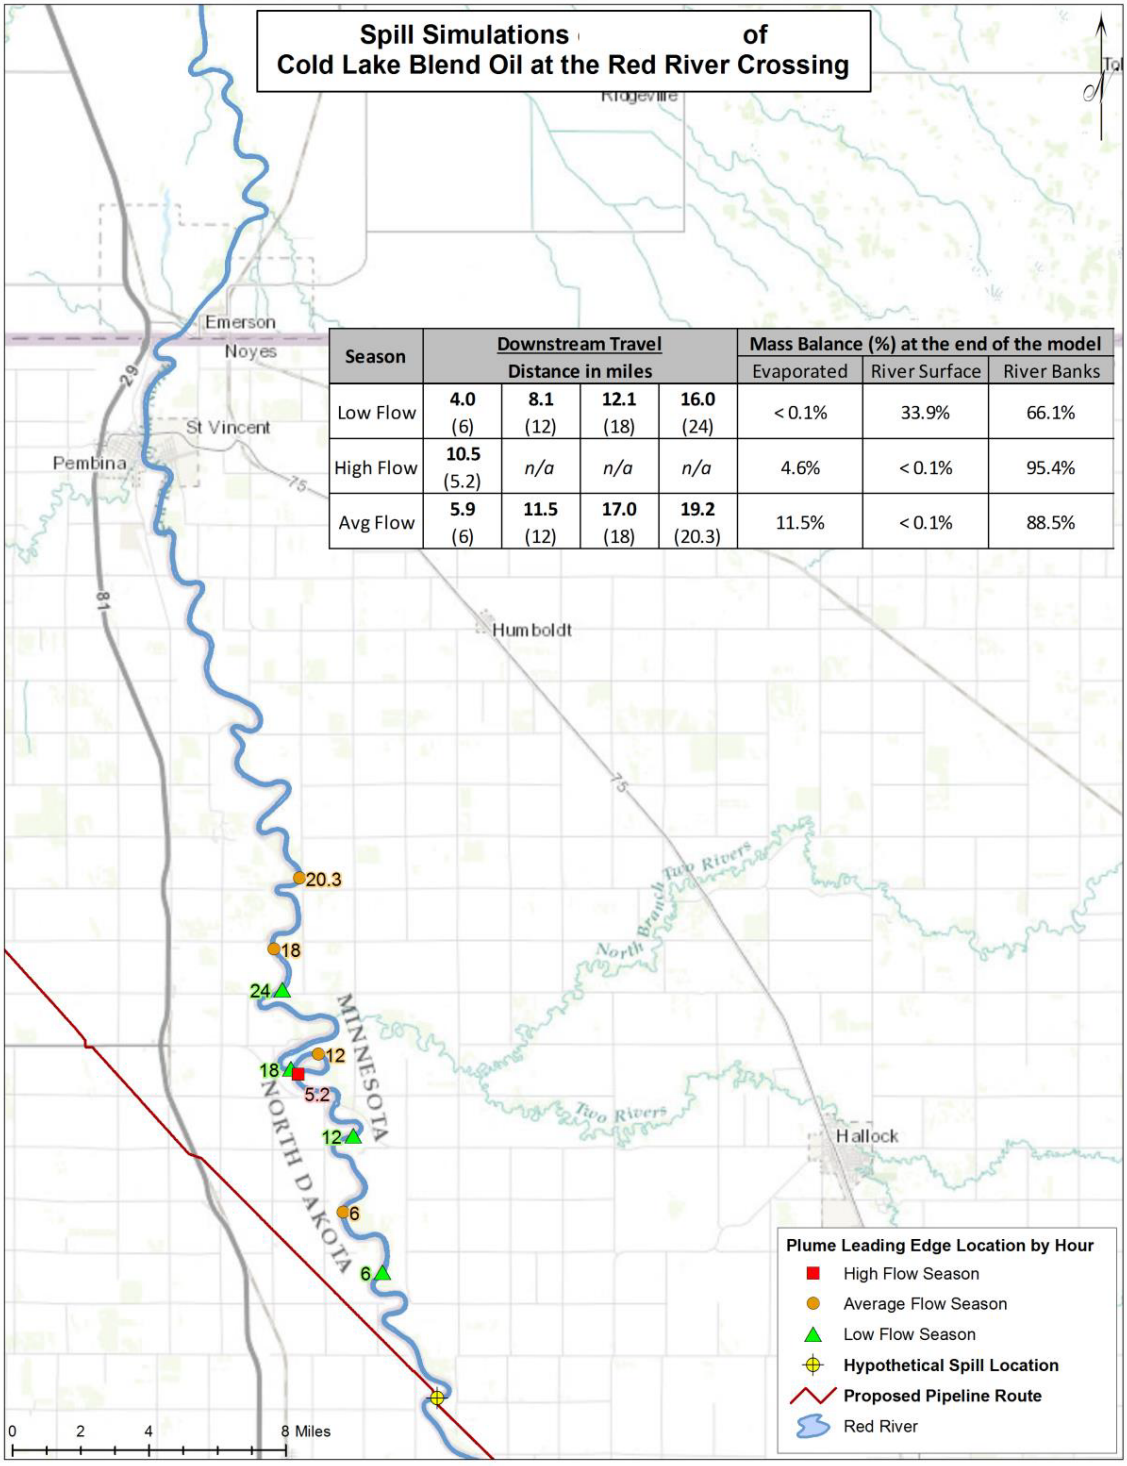
7.6.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils

A summary of the predicted downstream trajectory and mass balance of CLB and Bakken crude oils, under the three seasonal scenarios, is provided in Figures 7-6-6 and 7-6-7, respectively. These simulations are assumed to provide bounding conditions for a release of heavy or light crude oil types. The fate of most types of crude oil, if released, would lie within the envelope of predictions for the CLB and Bakken crude oil types. The Cold Lake crude oil was assumed to be CLSB for the high flow and average flow scenarios, and to be CLWB for the low flow (winter) scenario. As noted in Chapter 5.0, while OILMAP Land does provide an indication of the downstream extent of oiling and mass balance of oil within the modeled period, it does not quantify the amounts of oil components dissolved into the water column.

The maximum simulation duration using OILMAP Land was 24 hours, as it was assumed that emergency response measures to prevent or reduce further downstream transport of released oil would be in place within that length of time. Symbols on the drawings indicate the river seasonal flow condition (high corresponding to spring freshet, average corresponding to summer-fall conditions, and low corresponding to winter flow under ice). Numbers associated with the symbols indicate the predicted location of the leading edge of the released oil in the river after 6, 12, 18 or 24 hours. Numbers other than these (e.g., 20.3) indicate the time in hours of the predicted termination of downstream transport of the released oil due to adhesion or holdup of the oil along the river banks. Tables inserted within the Figures also provide information on the mass balance (i.e., oil remaining on the surface of the river, adhering to river banks, or evaporated to the atmosphere) of the released oil at relevant points in time after the start of the release.

7.6.5.1 Red River Release During High Flow (Spring) Period

Under the high river flow scenario, CLB was predicted to travel approximately 10.5 miles downstream in the Red River within 5.2 hours of the release (Figure 7-37). Beyond this point in time the model predicted that the oil would have been lost from the water surface, mainly as a result of adhesion to shoreline (95.4%), with the balance evaporating.



Bakken crude oil was predicted to be transported approximately 40.3 miles downstream within 18.5 hours of the release (Figure 7-38). The transport of floating oils was predicted to pass through

Pembina, ND and St. Vincent, MN, and into Canada. At this time, approximately 58.6% of the Bakken crude oil was predicted to adhere to shorelines and approximately 41.4% to have evaporated into the atmosphere. None of the oil was predicted to remain on the water surface after 24 hours of the release.

The release of Bakken crude oil under high flow conditions was predicted to result in oiling farther downstream than for the CLB. The difference in the extent of downstream transport was a result of the difference in the shoreline oil retention between the two oil types. Because of its higher viscosity and adhesiveness, larger amounts of CLB are predicted to strand, as a thicker layer of oil on a given length of shoreline, than for the Bakken crude oil. Conversely, the same amount of Bakken crude oil could affect a greater length of shoreline with a lesser thickness of oil, in addition to affecting a greater overall length of the river. This result is based upon the assumption of 100% shoreline oiling coverage (i.e., all shoreline was oiled to its maximum holding capacity as oil made its way downstream). In the event of an actual release, the downstream extents of CLB and Bakken crude may be more similar, and the effects of CLB may extend farther downstream than predicted, with patchy coverage.

A larger proportion of the Bakken crude oil was predicted to evaporate to the atmosphere than was predicted for the CLB. This was due in part to the lighter and more volatile character of the Bakken crude oil. In addition, the greater downstream transport of the Bakken crude oil took more time, and resulted in more water surface area with oil, both of which could allow more of the released oil to evaporate. Volatile components of the CLB would continue to evaporate after becoming stranded on shoreline, but this process was not included within the OILMAP Land model for stranded oil.

Figure 7-38 Predicted Downstream Transport of Bakken Crude Oil at the Red River Crossing Location

7.6.5.2 Red River Release During Average Flow (Summer-Fall) Period

Under average river flow, CLB crude oil was predicted to travel up to 19.2 miles downstream, within 20.3 hours of the release (Figure 7-37). After this time, there would be little CLB on the river's surface as the model predicted that most of the released oil would have stranded along shorelines (88.5%) or evaporated (11.5%). Emergency response measures to prevent further possible downstream transport of oil would be in place within 24 hours of the release.

Under average river flow, Bakken crude oil was predicted to be transported approximately 22.8 miles downstream, over the full 24-hour modeled period (Figure 7-38). Approximately 17.0% of the Bakken crude oil was predicted to oil the shorelines of Red River, with 46.2% predicted to evaporate into the atmosphere, and 36.9% to remain on the river surface at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude oil on the river surface after 24 hours could be expected to continue downstream. The oil would continue to weather and would oil shorelines until all of the oil was removed from the water surface.

Under average flow conditions, the CLB was predicted to travel farther downstream than during high river flow condition. This is a result of less interaction between the released oil and shorelines. Under average flow conditions the stream shorelines are assumed to be a mixture of grass and mud. Under high flow conditions, with water spreading into riparian areas, shorelines of the Red River are assumed to be vegetated. As a result, it was assumed in the modeling exercise that under average flow conditions, the shorelines would hold less of the viscous CLB oil type than during high flow conditions. The muddy shoreline present under average flow conditions is assumed to be capable of retaining about 150 bbl of CLB crude oil per mile of shoreline, whereas a grassy shoreline is assumed to be capable of retaining about 1,260 bbl of CLB crude oil per mile.

Slightly more of the released CLB crude oil was predicted to evaporate under the average river flow condition than under the high river flow condition (Figure 7-37). This difference is due largely to the warmer temperatures in the summer-fall season as compared to the spring freshet, as well as the shorter length of time that the oil was free on the water surface (i.e., the simulation for the average flow period terminated after 20.3 hours compared to the shorter duration of 5.2 hours for the high flow period.

When compared to the CLB under average river flow conditions, the Bakken crude oil was predicted to be transported farther downstream before reaching the 24 hour model limit of the simulation. This difference was attributable to the lower shoreline oil retention value for the low viscosity Bakken crude oil, when compared to the more viscous and adhesive CLB. Although not modeled here, it is expected that a medium crude oil would exhibit fate and transport properties intermediate between those of the Bakken and CLB crude oil types, with a tendency to behave more like the Bakken crude oil. This is because the viscosity and adhesiveness properties of a medium crude oil would typically be higher and, therefore, more similar to those of the Bakken crude oil, than to the CLB.

7.6.5.3 Red River Release During Low Flow (Winter) Period

Under low river flow conditions, CLWB was predicted to be transported a total of 16.0 miles downstream over the full 24-hour modeled period (Figure 7-37). Approximately 66.1% of the CLWB was predicted to become trapped under ice along the margins of the Red River, with 33.9% remaining in the river below the ice at the end of the 24 hour simulation. If left unmitigated, the CLWB remaining in the Red River after 24 hours could be expected to continue to move downstream until all of the oil was trapped along the river margins, or had accumulated in fissures and hollows in the river ice. This would provide only temporary storage of the oil, and oil would be expected to re-mobilize in response to changes in flow rates, and particularly during the spring breakup of ice. With the CLWB below the ice of the river, evaporation of oil to the atmosphere would be negligible in the short-term. However, emergency response measures to prevent further possible downstream transport of oil would be in place within 24 hours of the release.

Under low river flow, Bakken crude oil was predicted to be transported approximately a total of 16.0 miles downstream over the full 24-hour modeling period (Figure 7-38). Approximately 10.3% of the Bakken crude oil was predicted to become trapped along the river margins, while the remaining 89.7% was predicted to remain in the river, below the ice, at the end of the 24 hour simulation. If left unmitigated, the remaining Bakken crude oil in the river after 24 hours would be expected to continue to move downstream, with some accumulating along the river margins and some accumulated in fissures and hollows under the river ice.

As with the CLWB, the accumulation of released Bakken crude oil under the ice would be unstable, and oil would be expected to re-mobilize in response to changes in flow rates, and particularly during the spring breakup of ice. Evaporation of the Bakken crude oil to the atmosphere would also be negligible in the short-term. Less of the Bakken crude oil was predicted to accumulate at the river margins under the ice, when compared to the CLWB under low river flow conditions. This was due to the differences in shoreline oil retention between the two oils (i.e., lower viscosity and adhesion of the Bakken crude oil). For this reason, the Bakken crude oil was predicted to have greater mobility under the ice in winter.

7.6.6 Qualitative EHHRA for the Red River

In this section, the likely environmental effects of a crude oil release at the pipeline crossing location on the Red River are described. A worst case crude oil release from a mainline pipeline, such as described here, would be an unlikely event (Chapter 4.0). The proposed pipeline would carry a variety of crude oil types, ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumens such as CLB). Therefore, the following discussion describes the likely environmental effects of a crude oil release on relevant ecological and human environment receptors (identified in Section 7-6-3), using the predicted geographic extent of effects of released Bakken or CLB crude oil types over the 24 hour simulations as bounding conditions. Effects of season (including temperature, river flow conditions, and receptor presence/absence

and sensitivity) were also considered in the analysis. The rationale supporting the effects analysis, based on case studies describing the effects of crude oil releases on the various ecological and human environment receptors, was provided in Section 7.1 and Table 7-72.

7.6.6.1 Terrestrial Receptors

For this modeling scenario, the hypothetical release of crude oil is assumed to enter the Red River with no overland flow. Environmental effects on soils, terrestrial vegetation and groundwater quality are assumed to be localized, limited in spatial extent, and readily remediated using conventional clean-up techniques. The environmental effects of a crude oil release on land cover receptors will not be considered further for this scenario.

7.6.6.2 Aquatic Receptors

The aquatic environmental and ecological receptors that are considered in the assessment for the Red River are river water and river sediment quality, shoreline and riparian river bank habitat, benthic invertebrates, and fish.

Crude oil released to the Red River during the spring (high flow condition) is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas in the riparian floodplain as it moves north. The distance travelled would depend upon river flow and oil type. Based on OILMAP Land simulations, light oil is predicted to travel father downstream than heavy oil. For heavy oil, stranding on shore would be the primary fate, with only small amounts of evaporative weathering of the oil occurring within the first 24 hour period. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation.

The effects of oil releases on benthic invertebrates and fish depend on characteristics of the released oil and environmental conditions at the time of the release. Acute toxicity to fish is commonly but not always observed in association with crude oil releases, and is an indicator that, at least briefly, concentrations of dissolved hydrocarbons (particularly mono-aromatic hydrocarbons, some low molecular weight PAHs, and short-chain aliphatic hydrocarbons) are sufficiently high to cause acute toxicity due to narcosis. Light oils have low viscosity relative to heavier oils. Turbulence in the river water could potentially disperse the light oil as small droplets in the water column, increasing the potential for toxic fractions of the light oil to dissolve into the water column. As a result, the potential for acute toxicity to fish and invertebrates would be greater for the light oil than for heavier oils. However, the large volume of water flow associated with the spring period freshet in the Red River may also dilute and limit the maximum dissolved hydrocarbon concentration in water, as compared to periods of lower water flow.

There would also be high potential for chronic effects of released crude oil on fish eggs and embryos (i.e., induction of deformities or mortality collectively termed blue sac disease). Many of the fish species present in the Red River spawn in the spring and early summer. The eggs and embryos of these species could be exposed to total PAH concentrations in the river water that could be sufficiently high to induce deformities or cause mortality. In addition the potential for

phototoxicity, caused by an interaction of ultraviolet (UV) light with PAHs accumulated in fish tissues, would be greatest for a crude oil release in summer due to high light intensity and long day length. Small fish that are lightly pigmented or transparent (i.e., embryos, larval and juvenile fish) are most susceptible to phototoxicity. The risk of phototoxicity would be mitigated by high concentrations of suspended sediment present in the water of the Red River, which would reflect, scatter and absorb light, limiting the penetration of UV light into the water column.

Entrainment of small crude oil droplets in the water column also enhances the potential for light crude oils to interact with suspended sediment particles in the water column resulting in the formation of OPAs. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water, such as oxbows and backwaters. Formation of true oil-particle aggregates is less likely to occur with heavy crude oils such as diluted bitumen, as the higher viscosity of the oil precludes the ready formation of fine droplets in the water column (Zhou et al. 2015). However, heavy oils can still contact sediment particles along the shoreline, and some accumulation of both light and heavy oils in depositional areas is likely, although the precise mechanisms of deposition may vary. Neither crude oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release.

Crude oil released during the summer-fall (average flow) period is predicted to travel downstream, stranding on muddy river banks and losing volatile components of the oil to evaporation as it moves north. Results provided in Section 7.6.5 provide bounding cases for the products likely to be carried in the pipeline. The OILMAP Land simulations indicate that crude oil would be carried between 19.2 and 22.8 miles downstream from the point of release under summer-fall average-flow conditions. For heavy oil, stranding on shore would be the primary fate, with only small amounts of evaporative weathering of the oil occurring. For light oil, evaporation would be the primary fate, with a considerable amount of released oil potentially remaining on the surface of the Red River, and only a modest amount adhering to the river banks. The lower river flow in summer-fall compared to spring could result in higher concentrations of water soluble components in the river; however, along with lower flow rates, there would also be less turbulence in the water column and a reduced tendency for crude oil to be dispersed as fine droplets in the water column. As a result, and taking into consideration the relatively large size of the Red River, narcotic effects on fish and benthic invertebrates are unlikely during the summer season. Also taking into consideration the lower river flow and turbulence, deposition of crude oil residues to sediment in areas of still water is less likely during the summer season than during the spring period.

Crude oil released during the winter (low flow) period could potentially pool on the frozen river surface. If the release was to occur directly to the river below the ice (as is assumed in the OILMAP land model), or if there were openings in the ice that the released oil could penetrate, the oil could travel downstream under the ice, accumulating in the narrow gap between the ice and the river sediment, or accumulating in hollows under the ice as it moved north. Results provided in Section 7.6.5.3 provide bounding cases for the products likely to be carried in the pipeline. The OILMAP Land simulations indicate that crude oil would be carried approximately

16 miles downstream from the point of release under winter low-flow conditions. For both oil types, the winter ice would effectively inhibit evaporation, while providing greater potential for dissolution into the water column during the period of lowest dilution flow. The more viscous heavy oil would be predominantly trapped along the river margins, whereas a large fraction (about 33.9%) of the light crude oil would remain mobile at the interface between the river water and the underside of the ice. Therefore, a spill in winter could cause mortality to fish due to narcosis. This result would be more likely for the light crude oil, which would spread out over a larger area, than for the heavy crude oil, which would tend to remain in thicker localized accumulations. Fish eggs and larvae would generally not be present during the winter, so effects on these life stages due to blue sac disease are not likely, although crude oil residues in water and sediment could, if not adequately remediated, affect fish eggs and larvae in the following spawning season. Phototoxicity is not likely to occur following a release of crude oil in winter due to short day length and lower light intensity in winter, reflection and absorbance of light by snow and ice cover on the river, and absorbance of UV light by DOC in the water beneath the ice.

Both crude oil types could be accumulated in sediment, and both would be subject to re-mobilization with spring breakup of the ice, and increasing water flow rates.

7.6.6.3 Semi-Aquatic Wildlife Receptors

Habitat downstream of the hypothetical release location supports amphibians (e.g., salamander, mudpuppy), reptiles (e.g., turtles, snakes), semi-aquatic birds (e.g., ducks, geese) and semi-aquatic mammals (e.g., muskrat, otter). Details on predicted environmental effects for amphibians and reptiles, birds and mammals are provided below.

7.6.6.3.1 Amphibians and Reptiles

Crude oil released to the Red River during the spring (high flow) and summer-fall (average flow) seasons is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas. The distance travelled would depend on the flow conditions, as well as oil and shoreline type. The OILMAP Land simulations indicate that light oil will travel father downstream than heavy oil. A crude oil release during the summer-fall period would not be likely to have direct effects on riparian habitat and, therefore, effects on reptiles (e.g., snakes) in the riparian zone would be minimal. Downstream transport of released crude oil in summer-fall would not travel as far north as in spring (between 19.2 and 22.8 miles downstream from the point of release) meaning that possible oil-organism interactions would be fewer in this season than in spring.

Within the oil-exposed habitats along the river that support amphibians (adults, juveniles, and eggs), oiling effects including mortality would be observed. Turtles appear to be relatively tolerant of external crude oil exposure, and although these animals are likely to become oiled, mortality of turtles as a result of this exposure is less likely. Reptiles like lizards and snakes are primarily terrestrial species and are less intimately associated with aquatic environments. As a result, exposure of these animals to released crude oils would be limited. After the Kalamazoo River oil spill in 2010 snakes did not appear to be highly exposed to spilled oil. A release of light

crude oil during the spring would likely have a greater effect than in summer due to the greater predicted downstream transport distance and interaction with greater areas of riparian and wetland habitats than later in the year.

Amphibians and reptiles undergo a winter dormancy period when temperatures drop below approximately 41 to 45°F. At this time, amphibians and turtles typically bury themselves in river bottom substrates or other similar habitats. Therefore, during the winter (and likely up until April or May when winter ice is gone), these animals would have very little exposure to released oil moving on the water surface or within the water column.

7.6.6.3.2 Birds

Aquatic and semi-aquatic birds are those that use rivers, wetlands, and riparian areas as components of their habitats, particularly for nesting and feeding. These birds belong to a variety of guilds including but not limited to waterfowl, divers, gulls and terns, raptors, shorebirds, waders, and some songbirds. They have a variety of dietary preferences, including piscivory, insectivory, omnivory and herbivory. What they have in common is that if exposed to external oiling, their ability to maintain body temperature may be compromised, leading to death as a result of hypothermia. Even if they survive their initial exposure to crude oil, the exposure may require an increase in metabolic rate to survive. In turn, this may compromise other life functions such as reproduction or growth. Birds that survive external oiling may experience toxicological stresses as a result of ingesting crude oil residues while preening or attempting to clean and restore the normal properties and functions of feathers. Birds can also transfer potentially lethal quantities of crude oil residue from their feathers to the external surface of eggs, resulting in death of developing embryos.

Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species which leave their summer (and often breeding) habitat in the fall for wintering areas farther south where they can find open-water habitat. However, some birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available. Timely capture and rehabilitation of oiled birds may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, many migratory birds would be returning to riverine habitats in Minnesota and North Dakota, or migrating through these areas on their way to breeding habitats farther north. With cold water temperatures prevailing, aquatic and semi-aquatic birds contacted by crude oil are likely to die as a result of hypothermia. Only birds in the affected river reach, which could range from 10.5 to 40.3 miles in extent, would be affected; birds upstream, farther downstream, or occupying other nearby habitats would likely be less affected as it is assumed that emergency response measures to prevent or reduce further possible downstream transport of oil would be in place within 24 hours of the release.

Environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude. With rising water temperatures, mortality of lightly oiled adult birds due to

hypothermia becomes less likely than in the spring. However, in the early summer, environmental effects could include egg mortality due to transfer of oil from the feathers of lightly oiled adult birds in the nest. Chronic adverse effects on the health of birds that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while preening, or while consuming food items. However, as in the spring, effects are expected to be limited to areas where birds can physically contact oil, which could range from 19.2 and 22.8 miles downstream along the Red River from the release point.

In the winter months, ice cover on the Red River would strongly limit the opportunities for aquatic and semi-aquatic birds to occupy this habitat. Therefore, adverse effects on the health of aquatic and semi-aquatic birds are not likely for a release of crude oil during the winter.

7.6.6.3.3 Semi-aquatic Mammals

While the semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, this assessment focuses on species that have a primary association with the aquatic environment such as muskrat and beaver (herbivores), American mink (carnivore-piscivore) and river otter (piscivore). These species are at more likely to come into contact with an oil release in water than terrestrial mammals.

Effects to semi-aquatic mammals are typically described in terms of direct physical effects (e.g., hypothermia due to loss of insulation), direct toxicological effects (e.g., gastro-enteropathy caused by ingestion of crude oil residues while grooming oiled fur or ingesting food), and indirect effects caused by changes to habitat (e.g., land cover and food availability). The spatial extent along the Red River where effects may occur, and the magnitude of effects, is related to the type of oil released, season and flow rate. Effects on semi-aquatic mammals relate more to the amount of time spent in the water (and consequent exposure to physical oiling) than to dietary preferences. Timely capture and rehabilitation of oiled mammals may help to mitigate the environmental effects of a crude oil release.

During the spring (high flow) season, with cold water temperatures prevailing, semi-aquatic mammals contacted by crude oil are likely to die as a result of hypothermia. Based on the OILMAP Land simulations, the potentially affected river reach could range from 10.5 to 40.3 miles in extent. Therefore, although mortality of a considerable number of semi-aquatic mammals could be expected, large-scale (i.e., regional) population level effects are unlikely. Environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude than in spring. With rising water temperatures, mortality of lightly oiled semi-aquatic mammals due to hypothermia is less likely. Chronic adverse effects on the health of semi-aquatic mammals that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while grooming, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure.

In the winter months, muskrat and beaver are likely to reduce their activity levels, although American mink and river otter would remain active. Animals that became oiled in the winter would likely die rapidly as a result of hypothermia.

7.6.6.4 Human and Socio-Economic Receptors

Crude oils are complex mixtures of hydrocarbon compounds. Light crude oils typically contain more VOCs as compared to heavier crude oils, although diluted bitumen may contain similar amounts of VOCs to some light crude oils, depending upon the type and amount of diluent. Air quality in the vicinity of a crude oil release, and along the downstream corridor, would be affected by the release of VOCs (such as benzene, which is often used as an indicator substance) primarily within the first 24 hours of an oil release. The communities of Pembina, North Dakota and St. Vincent, Minnesota could potentially be exposed to hydrocarbon vapors under certain circumstances, and were identified through the HCA analysis as being "other" (i.e., smaller) population areas. Under high flow conditions in the Red River, the OILMAP Land modeling indicated that the leading edge of released Bakken crude oil could reach these urban areas in under a day. Setbacks afforded by the riparian floodplain of the river generally assure that residences are approximately 120–140 yards away from the river as it passes through Pembina and St. Vincent, although this distance would be reduced during the spring freshet. Under the winter release scenario, the ice cover is assumed to strongly limit release of volatile hydrocarbons to air.

Typical human health effects associated with short-term (acute) inhalation of volatiles from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term or repeated skin contact with crude oil may result in dermatitis. The case studies (Section 7.1) do not reveal any instances of human fatality as a result of inhalation of crude oil vapor. Similarly, ATSDR (1995) reports that there are no known instances of human fatality as a result of inhalation of vapor from fuel oils, which would be comparable to light crude oils.

The potential for inhalation exposures to the public would be greatest near and downwind from the release site while the released oil is on the water surface (i.e., 3 miles east of Bowesmont, North Dakota and 9 miles southwest of Hallock, Minnesota, as well as near the Red River). There are three residences within a mile of the proposed Red River crossing location. In the unlikely event of a crude oil release, residents close to or downwind of the release trajectory would become aware of a strong hydrocarbon odor.

Most of the volatile hydrocarbons would be lost within the first 24 hours following a release of crude oil. Actual or potential exposure to crude oil vapor may result in residents leaving, or being advised to leave their homes for a period of time while emergency response takes place.

The HCA analysis did not identify drinking water intakes that could be affected downstream of the Red River crossing. Based on a search of municipal water supplies for Pembina, North Dakota and St. Vincent Minnesota, it appears that neither of these communities consistently obtains drinking water from the Red River. Rather, people in Pembina, North Dakota can

purchase drinking water from the Northeast Regional Water District (http://www.northeastregionalwater.com/index.html) and drinking water is supplied to St. Vincent by the North Kittson Rural Water company (http://www.health.state.mn.us/divs/eh/water/com/waterline/featurestories/ruralwater.html). In the unlikely event of a crude oil release, notifications would be sent to people in the area so that drinking water intakes (should there be any) could be suspended if required.

Relatively little has been published regarding the long-term effects of exposure by humans to crude oil releases. Health effects observed in residents and clean-up workers in the months following an oil release generally do not persist over the long term (Eykelbosh 2014). The International Agency for Research on Cancer (IARC 1989) has determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans. Although toxicological effects from short-term exposure to volatile hydrocarbons are reversible when exposure is reduced, other health effects such as anxiety and depression may occur, and may persist, regardless of whether the individual was physically exposed to hydrocarbons.

Effects of a crude oil release on human receptors would generally be similar for the spring (high flow) and summer-fall (average flow) seasons. In summer, the warmer temperatures and slower river flow velocities in the summer would promote more rapid evaporation of volatile hydrocarbons in a smaller area. In the spring freshet period, higher river flow velocity would transport the released oil farther downstream within the first 24 hours, potentially resulting in effects to a larger number of people. The flow modeling suggests that the light crude oil (Bakken) is likely to be transported farther downstream within 24 hours than the heavy crude oil (Cold Lake diluted bitumen). As a result, a release of the light crude oil may affect a larger number of individuals than a release of the heavy crude oil type. Both Bakken crude oil and Cold Lake diluted bitumen are expected to contain similar overall amounts of volatile hydrocarbons, so differences related to the type of released oil are likely to be minor.

No overland transport of released crude oil was modelled for this hypothetical release location. Infiltration of crude oil into soil and subsequently into groundwater would be limited.

During the spring freshet period, the Red River is susceptible to flooding and can overtop its banks and spread into the surrounding farmland. A release of light and medium crude oils during this period would provide a potential pathway for oil deposition to soil in low-lying areas. Light and medium crude oils would be expected to become dispersed over a large area, and are readily biodegraded, so that persistent accumulation of these oil types in riparian areas or temporarily flooded farmland is unlikely. Heavy crude oils and diluted bitumen are more likely to be deposited as thicker layers of more persistent oil, and would likely require more active remediation of affected areas. Soils in the area are predominantly lacustrine clays, silts, and sands (MN DNR 2006) and these soils typically have low to medium permeability (compared to sand/gravel soils). Therefore, penetration of crude oil into flooded soils, and effects on groundwater quality (as a potential source of potable water) are unlikely.

The Red River provides recreational opportunities (e.g., fishing, hunting, boating, swimming, camping) at many locations north of the release location. Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. Fisheries regulators and public health officials typically close fisheries until it is confirmed through monitoring that fish consumption is not a threat to public health. This standard approach is an effective mitigation strategy to protect human receptors for contact with constituents in the oil.

7.6.6.5 Summary and Conclusions

Expected environmental effects to key ecological and human environment receptors after a hypothetical large crude oil release to the Red River were assessed for both light crude oil (e.g., Bakken crude oil) and heavy crude oil (e.g., diluted bitumens such as CLB). The discussion of expected environmental effects on receptors is based on these crude oil types as bounding conditions.

Potential terrestrial receptors, aquatic receptors, semi-aquatic wildlife receptors and human and socio-economic receptors were screened to identify those with the most likely interactions with released oil. Selected receptors for qualitative assessment are highlighted in Table 7-72, discussed in detail in Sections 7.6.6.1 to 7.6.6.4, and summarized here in Table 7-74.

Table 7-74 Environmental Effects Summary Table for Pipeline Crude Oil Releases

Receptor	Expected Environmental Effects of Released Crude Oil	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Terrestrial Receptors			
Soils	It is assumed in the model that oil would enter directly into the Red River with no hold up of oil on land. In the event of an actual oil release, any oil on land would undergo prompt and effective remediation. Residual effects on plant communities, soil or groundwater quality are unlikely.	SAME	SAME
Groundwater		SAME	SAME
Terrestrial Vegetation		SAME	SAME
Aquatic Receptors			
Rivers	Both light and heavy oil would travel downstream from the release location. Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, but would be thinner on the water and less persistent where they contact shoreline. Both light and heavy crude oils are predicted to travel similar travel distances under winter conditions, although the heavy oil would be likely to remain trapped along the river edges. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column, meaning potentially toxic fractions of the light oils would more readily dissolve into the water column.	MORE	LESS
Sediment	Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, with both oil types travelling similar distances under winter conditions. Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. The low viscosity of the lighter type crude oils could potentially result in a larger amount of oil entrainment as fine droplets as compared to heavier blends, resulting in the formation of oil-particle aggregates, which could both sink, and enhance biodegradation. Such aggregates may subsequently be preferentially deposited in areas of still or slowly moving water. There also exists the potential for low molecular weight aromatic hydrocarbons to dissolve into the water column, as well as greater potential for deposition of hydrocarbons to the sediment. Under winter conditions, more of the heavy crude oil is predicted to become trapped along the river margins, and this oil is also likely to interact with sediment, resulting in mixing of oil and sediment, or formation of oil-particle aggregates. However, the spring freshet is also a major seasonal factor that can flush river sediments leading to a rapid restoration of damaged habitat, and dispersal of oil-particle aggregates in a way that enhances natural recovery.	LESS	MORE

Table 7-74 Environmental Effects Summary Table for Pipeline Crude Oil Releases

Receptor	Expected Environmental Effects of Released Crude Oil	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Shoreline and Riparian Areas	Both light and heavy oil would travel downstream from the release location. Lighter crude oils are expected to travel farther downstream than heavier crude oils in spring and summer conditions, but would be thinner and less persistent on the water. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. For heavy oil, stranding on shore would be the primary fate. For light oil, stranding would remain the primary fate, but considerably more of the released oil could be lost to evaporation. Flooding of riparian and wetland habitat in spring could lead to stranding of crude oils in this habitat, with heavy crude oil likely to be deposited as patties or tar balls. This is in contrast to light crude oil which would be deposited as a thin layer or sheen.	LESS	MORE
Aquatic Plants	The high suspended sediment load of the Red River limits light penetration and opportunities for the development of a substantial aquatic plant community. Therefore, effects on aquatic plant communities would be minor.	SAME	SAME
Benthic Invertebrates	Environmental effects on benthic invertebrates would be limited to areas affected by the released oil. In the short-term, the low viscosity of light crude oil would result in greater potential for oil entrainment as fine droplets, as compared to heavier blends. This would enhance dissolution of low molecular weight aliphatic and aromatic hydrocarbons into water (with resulting acute toxicity), in addition to promoting oil-particle interaction and potential deposition of oil to sediment. For heavy crude oil, there would be less potential for dissolution of hydrocarbons into the water, but greater long-term potential for deposition of tar balls and patties as a result of oil interaction with sediment. These could accumulate in depositional areas, resulting in chronic effects on benthic invertebrates.	MORE	LESS
Fish	Environmental effects on fish would be limited to areas affected by the released oil. Light oils have low viscosity relative to heavier oils and turbulence in the river water could potentially disperse the light oil as small droplets in the water column. This would enhance the dissolution of potentially toxic fractions of the light oil into the water column. As a result, the potential for acute toxicity to fish due to narcosis would be greater for the light oil than for heavy oil. Potential chronic effects on fish eggs and embryos (e.g., Blue Sac Disease) could also occur, but would be most likely to occur in spring and early summer, when most species spawn. The potential for phototoxicity, caused by an interaction of ultraviolet light with PAHs accumulated in fish tissues, would be greatest in summer due to high light intensity and long day length. However, the high turbidity of the Red River would act to limit light penetration, reducing this risk.	MORE	LESS

Table 7-74 Environmental Effects Summary Table for Pipeline Crude Oil Releases

Receptor	Expected Environmental Effects of Released Crude Oil	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Semi-Aquatic Wildlife Receptors			
Amphibians and Reptiles	Environmental effects on amphibians and reptiles would be limited to areas affected by the released oil. Light crude oil is expected to travel farther downstream under spring and summer conditions than heavy crude oil, but would be thinner and less persistent on the water. Crude oil released under ice during the winter would not contact shoreline or riparian areas, although crude oil that was not recovered could be dispersed over a large area during the spring freshet. Flooding of riparian habitat in spring could lead to stranding of crude oils in this habitat. Within these habitats, oiling effects on adults, juveniles, and eggs could potentially be observed. Higher potential would exist for effects on amphibians than for turtles, which appear to be somewhat tolerant of external oiling. Dormancy of amphibians and reptiles in winter and early spring means exposure to oil released at this time of year could be negligible, and adverse environmental effects unlikely.	MORE	LESS
Birds	Mortality of oiled aquatic and semi-aquatic birds would be limited to areas affected by the released oil. Few birds are present in winter, so effects would be reduced in that season. Released light crude oil is generally transported farther than heavy crude oil, so environmental effects could be more spatially extensive for light crude oil types. Cold water in the spring, in combination with greater downstream movement of released oil, suggests that environmental effects of released oil could be greatest for a light crude oil in spring, and of lesser magnitude for a heavy crude oil release.	MORE	LESS
Semi-aquatic Mammals	Mortality of oiled semi-aquatic mammals would be limited to areas affected by the released oil. Released light crude oil is generally transported farther than heavy crude oil, so environmental effects could be more spatially extensive for light crude oil types. Cold water in the spring, in combination with greater downstream movement of released oil, suggests that environmental effects of released oil could be greatest for a light crude oil in spring, and of lesser magnitude for a heavy crude oil release. Adverse effects on mink and otter would be particularly severe in winter, due to the effects of oil on the insulating properties of fur, in combination with cold water temperatures. However, muskrat and beaver might be spared due to their lower activity levels in winter.	MORE	LESS

Table 7-74 Environmental Effects Summary Table for Pipeline Crude Oil Releases

Receptor	Expected Environmental Effects of Released Crude Oil	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Human and Socio-Economic Receptors			
Air Quality	Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns. Light crude oils typically contain more VOCs than heavier crude oils, although the VOC content of diluted bitumen may be similar to that of light crude oil, depending on the type and quantity of diluent used in its manufacture. Air quality in the vicinity of the oil release would be most affected within the first 24 hours of an oil release. Under winter conditions, ice cover would strongly limit or prevent evaporation of crude oil vapors to the atmosphere.	MORE	LESS
Human Receptors	Typical human health effects associated with short-term (acute) inhalation of VOCs from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain; fatality is not expected. Residents in close proximity would become aware of a strong hydrocarbon odor that would alert them to the presence of a hazard. Most volatile hydrocarbons would be lost within 24 hours following a release. Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health. Under the winter release scenario, ice cover is assumed to strongly limit release of volatile hydrocarbons to air. Other population area HCAs were identified along the path of the release. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route.	MORE	LESS
Public Use of Natural Resources	Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Light crude oil is predicted to be transported farther downstream than heavy crude oil during the first 24 hours following a release, affecting a larger area. However, the heavy crude oil would form thicker and more persistent deposits where it contacted shoreline and riparian areas. This conclusion is independent of the type of crude oil that could be released.	SAME	SAME

7.7 EXPECTED ENVIRONMENTAL EFFECTS OF LARGE RELEASES OF CRUDE OIL TO THE MISSISSIPPI RIVER AT PALISADE

The proposed pipeline could potentially cross underneath the Mississippi River approximately one mile south of Palisade, Minnesota and immediately east of Route 10. This scenario captures a hypothetical release of crude oil directly to the Mississippi River, with downstream transport to the south and west. The Mississippi River near the release point is relatively flat and contains many oxbows, many of which are known areas of interest for recreational uses of the river (MN DNR 2016m). The Mississippi River passes through mixed farmland and state forest as it flows towards Aitkin, Minnesota. The town of Aitkin is protected from potential floods by a diversion channel, which would presumably be carrying some of the flow of the Mississippi River during the spring freshet period, although not necessarily at other times of the year. As identified in Chapter 4.0, the Mississippi River crosses through the Tamarack Lowlands, a low-lying subsection of the Northern Minnesota Drift and Lake Plains Section that is part of the greater Laurentian Mixed Forest Province.

7.7.1 Description of the Freshwater Environment

The Mississippi River near Palisade, Minnesota flows to the south and west along a winding channel through terrain that is largely flat. The river has a well-defined channel, although there are numerous oxbows and side channels that, depending upon river flow, may or may not be hydraulically connected to the main channel. The river channel near the hypothetical release point is about 180 to 200 ft wide. The banks are mainly forested (ranging from a narrow riparian strip of trees, to extensive woodland on some oxbow peninsulas). Land use outside of the immediate floodplain is mainly agricultural on both sides of the river. Low lying areas of the Mississippi River are subject to flooding (MN DNR 2016m); there are only a few residences in close proximity to the river, and these appear to be predominantly associated with farms.

Downstream of the hypothetical release location, and north of Aitkin, Minnesota, is a spillway and flood diversional channel that transmits water from the Mississippi River upstream of Aitkin, to a point on the same river downstream of Aitkin, a distance of approximately 5.8 miles. The entrance to the flow diversional channel appears to be a passive spillway, with a constriction at the entrance so that water would pass through a narrows approximately 50 ft wide. When the river is in flood stage, some of the water would pass through the spillway, where there would be turbulent flow. However, none of the modeled crude oil release trajectories was predicted to reach the entrance of the flow diversion channel within 24 hours of a hypothetical release event. The average velocity of the Mississippi River changes with season, with slowest velocities (e.g., about 0.74 mph) expected during low flow periods in the winter, and only slightly greater velocities (e.g., about 1 mph) during the spring high flow period.

The vegetative communities in the river oxbows include speckled alder, willows, bog birch, ferns, tall asters, sedges, and wildflowers. Some of the oxbows are covered by forest; others appear to be maintained at an earlier successional stage, possibly due to disturbance caused by periodic flooding. The still waters of the oxbows provide pond and marsh habitat suitable for muskrat, as well as providing spawning and rearing habitat for fish such as northern pike (MN DNR 2016n). Muskrat, beaver, otter, turtles, herons, hawks, osprey, and eagles are commonly observed along the river (MN DNR 2016n).

In this stretch of the Mississippi River, northern pike, walleye, bass and muskellunge are abundant (MN DNR 2016n; MN DNR 2010b). The Tamarack Lowlands Subsection provides important wintering areas for boreal birds in times of food shortage and is home to a predicted 69 SGCN. These include birds (51 species), fish (3 species), insects (5 species), mammals (4 species), mollusks (2 species), reptiles (2 species), and spiders (1 species) (MN DNR 2006). Of these species, 16 are afforded federal or state endangered, threatened, or of special concern status (MN DNR 2006; MN DNR 2016d). It is foreseeable that some of these SGCN could utilize aquatic habitats along the Mississippi River.

The Mississippi River crosses through portions of the Waukenabo State Forest, and sections of land owned by the Bureau Land Management (BLM). The most common land uses in the Tamarack Lowlands Subsection are forestry, tourism, and outdoor recreation, agriculture, and peat mining (MN DNR 2006).

Several access points downstream from the proposed pipeline crossing location were visited in May, 2016, to provide additional insight into baseline environmental conditions for Mississippi River and surrounding environments. Representative site photographs are provided in Figure 7-39 through Figure 7-42. Field observations are summarized in Table 7-75.

Figure 7-39 Mississippi River and Riparian Habitat Approximately 5 Miles Downstream of Pipeline Crossing

Figure 7-40 Mississippi River and Riparian Habitat Approximately 5 Miles Downstream of Pipeline Crossing

Figure 7-41 Mississippi River and Riparian Habitat Approximately 30 Miles Downstream of Pipeline Crossing

Figure 7-42 Mississippi River and Riparian Habitat Approximately 61 Miles Downstream of Pipeline Crossing

Table 7-75 Environmental Characteristics Observed at Selected Access Points on the Mississippi River in May 2016

Access Point	Latitude Longitude	Notes
County Road 10 approximately 3.5 miles east of US Hwy 169 and 5 miles downstream of proposed pipeline crossing	46.709591 -93.484909	*Habitat Description:* River banks are approximately 10 ft high and relatively steep in most areas. Vegetation adjacent to river channel is a mix of floodplain forest (silver maple, cottonwood dominant) with floodplain wet/sedge meadow. Sandbar willow is common in some areas adjacent to the stream channel. The invasive, nonnative reed canary grass occurs occasionally here. *Wildlife observed:* American robin, Baltimore oriole
Mississippi River at Aitkin state water access site, just north of Aitkin, approximately 30 miles downstream of proposed pipeline crossing	46.5424 -93.7131	*Habitat Description:* Plant communities in the vicinity of this location include floodplain forest (silver maple-box elder) and terrace forest (bur oak, elm, green ash). Herbaceous vegetation is generally dominated by natives (especially sedges), but the invasive, nonnative reed canary grass occurs occasionally. *Wildlife observed:* blue jay
Mississippi River at Highway 6 state water access site; 5 miles north of Crosby at southwest corner of bridge and approximately 61 miles downstream of pipeline crossing.	46.5435 -93.9564	*Habitat Description:* River bank is relatively steep and approximately 10-15 ft high. Floodplain forest is present in the lowest areas adjacent to the river. However, due to the high banks of the river, much of the adjacent vegetation is terrace forest (mesic to dry-mesic oak forest with aspen) on sandy soils. *Wildlife observed:* crow, blue jay

7.7.2 High Consequence Area Assessment for the Mississippi River near Palisade Crossing Location

As defined in Section 7.0, HCAs include populated areas, drinking water source areas, ecologically sensitive areas, and commercially navigable waterways. Sensitive AOIs include Minnesota drinking water management areas, native plant communities, sensitive lake shores, recreational areas, tribal lands, and protected areas of several types (e.g., national forests, military lands, state parks).

Under low and average flow conditions, floating plumes of CLB and Bakken crude oil are not predicted to pass HCAs. However, under high flow conditions, floating plumes of both oil types are predicted to pass through habitat that has been identified as an environmentally sensitive area (Table 7-76). The Mississippi River downstream of Palisade also flows through several protected areas and environmental AOIs (Table 7-77). As with the HCAs, floating plumes of CLB and Bakken crude oil under low flow conditions are not predicted to pass the AOIs. However, under average and high flow conditions, both oil types are predicted to pass BLM lands and the

Waukenabo State Forest (Table 7-77). The locations of the HCAs and AOIs are shown in Figure 7-43.

Table 7-76 HCAs Potentially Affected by a Release of CLB and Bakken Crude Oil at the Mississippi River near Palisade Crossing Location

HCA Type	HCA Subtype	Description / Locations
Environmentally Sensitive Area	N/A	N/A
NOTE: Data for the HCA analysis were obtained from the USDOT PHMSA HCA datasets plus additional HCAs compiled by Enbridge during 2010 and 2013.

7.7.3 Selection of Key Ecological and Human Environment Receptors for Mississippi River near Palisade Crossing Location

Taking into account environmental characteristics of the Mississippi River near Palisade, the potential interactions of released crude oil with key ecological and human environment receptors were screened to identify key receptors for the subsequent environmental effects analysis. The rationale and results of this screening step are provided in Table 7-78.

Table 7-78 Key Ecological and Human Environment Receptors for the Mississippi River near Palisade

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mississippi River near Palisade Scenario	Selected (Y/N)
Terrestrial Receptors		
Soils	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with no holdup of oil on land. Any oil that reaches soil would be physically remediated to established standards.	N
Groundwater	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with no holdup of oil on land. In the event of an actual oil release, effects on groundwater quality would be localized and/or negligible.	N
Terrestrial Vegetation	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with no holdup of oil on land. Any oil that reaches soil would be physically remediated and vegetative cover would be restored as part of the cleanup process.	N
Aquatic Receptors		
Rivers (Mississippi River)	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver.	Y
Lakes	Low. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver. There is no relevant lacustrine habitat in the vicinity of the predicted release trajectory.	N
Sediment	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver. This allows potential interaction and/or deposition of crude oil residues to sediments.	Y
Shoreline and Riparian Areas	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver. This allows potential interaction with shoreline and riparian habitat.	Y
Wetlands	High. An assumption made in the fate modeling for this scenario is that released oil would enter directly into the Mississippi River with subsequent physical transport downriver and potential interaction with wetlands along the river and oxbows.	Y

Table 7-78 Key Ecological and Human Environment Receptors for the Mississippi River near Palisade

Receptor	Relevance for Inclusion as an Environmental Receptor for the Mississippi River near Palisade Scenario	Selected (Y/N)
Aquatic Plants	High. Mississippi River supports aquatic plant communities.	Y
Benthic Invertebrates	High. Mississippi River supports benthic invertebrate communities.	Y
Fish	High. Mississippi River supports fish communities.	Y
Semi-Aquatic Wildlife Receptors		
Amphibians and Reptiles	High. Mississippi River supports amphibians and reptiles.	Y
Birds	High. Mississippi River supports waterfowl and other birds.	Y
Semi-aquatic Mammals	High. Mississippi River supports semi-aquatic mammals.	Y
Human and Socio-Economic Receptors		
Air Quality	High. The community of Palisade, Minnesota is approximately one mile north of the hypothetical release location. Some homes are located along the downstream flow path for released crude oil. Effects on air quality have the potential to temporarily disrupt human use and occupancy patterns.	Y
Human Receptors	High. The community of Palisade, Minnesota is approximately one mile north of the hypothetical release location. Some homes are located along the downstream flow path for released crude oil. Effects on air quality or the presence of crude oil residues in aquatic and riparian habitat have the potential to temporarily affect human health.	Y
Public Use of Natural Resources	High. The Mississippi River near Palisade, Minnesota is shared by the Waukenabo State Forest. The drinking water intake for Palisade is upstream of the hypothetical release location so effects on water quality for residences in the area are not expected. Effects on air and water quality, or the presence of crude oil residues in the sediment, riparian or wetland habitat, could potentially disrupt public use of natural resources (e.g., drinking water supplies, hunting, fishing, recreation).	Y

7.7.4 Modeled Conditions at the Release Location

A description of key modeling assumptions for the environmental effects analysis for the Mississippi River near Palisade, Minnesota scenario is provided in this section. The Mississippi River channel downstream from the hypothetical release location is characterized by low gradient and relatively flat water. The flood diversion channel with its dam and spill way has the potential to result in localized turbulence that could entrain crude oil, should it be released and transported downstream that far. Unlike OILMAP Land, the SIMAP fate and transport modeling software can quantify the amount of crude oil that is likely to become entrained into or

dissolved in the water column, or deposited to sediments as a result of the turbulent conditions (Chapter 4 and 5). To shed additional light on this potential, SIMAP was used to simulate hypothetical releases of CLB and Bakken crude oils into the Mississippi River downstream of Palisade, Minnesota (and also at Little Falls, Minnesota). Like the OILMAP Land model, SIMAP also provides an indication of the downstream extent of oiling and mass balance of oil within the 24 hour modeled period. A longer time period was not modeled as it was assumed that emergency response measures to prevent or reduce further downstream transport of released oil would be in place within the 24 hour period.

The two crude oil types used in this analysis provide bounding cases for oils that range from light (e.g., Bakken crude oil having low viscosity and density) to heavy (CLB/CLWB, diluted bitumen crude oil types having higher viscosity and density). Seasonal variations in river flow velocity, temperature, wind speed, and snow and ice cover were all considered at the release location. A summary of key variables is provided in Table 7-79.

Table 7-79 Environmental and Hydrodynamic Conditions for the Three Modeled Periods at the Mississippi River at Palisade Crossing

Season	Month	Air Temperature (°C)	Wind Speed (m/s)	Average River Velocity (m/s)
Low Flow (Winter)	March	-3.19	4.78	0.33
Average Flow (Summer)	July	20.19	3.95	0.38
High Flow (Spring)	April	5.03	5.24	0.47
NOTE: A velocity of 1 m/s is equivalent to 2.25 miles per hour.				

The highest average flow rate of the Mississippi River downstream of Palisade coincides with the spring freshet (i.e., April-June), a result of rising temperatures and snowmelt. Average flow would typically occur in summer and fall seasons. July, the month with the warmest temperature, was selected to represent the maximum amount of evaporation. The lowest flow rate occurs in winter (March), and was typified by freezing conditions and probable ice cover on water.

The crude oil release volume was calculated as a full bore rupture, with a maximum time to response in the pipeline Control Center of 10 minutes, followed by a 3-minute period to allow for valve closure. The release volume therefore represents the volume of oil actively discharged in the period of time required to detect and respond to the event (taking into consideration the pipeline diameter, pipeline shutdown time, pipeline design flow velocity), followed by the volume of oil lost due to drain-down of the elevated segments of pipeline. The maximum 13-minute response time to valve closure is an Enbridge standard for safe operations and leak detection. This includes the combination of identification of the rupture, analysis of the pipeline condition, pipeline shutdown, and full valve closure in the affected pipeline section. While 13 minutes is the maximum time for valve closure, this is a conservative assumption, since a

response through to valve closure is expected to occur in less than 13 minutes in a full bore rupture leak scenario. Based on these assumptions, the site-specific hypothetical release volume was estimated of Bakken, CLB, or CLWB.

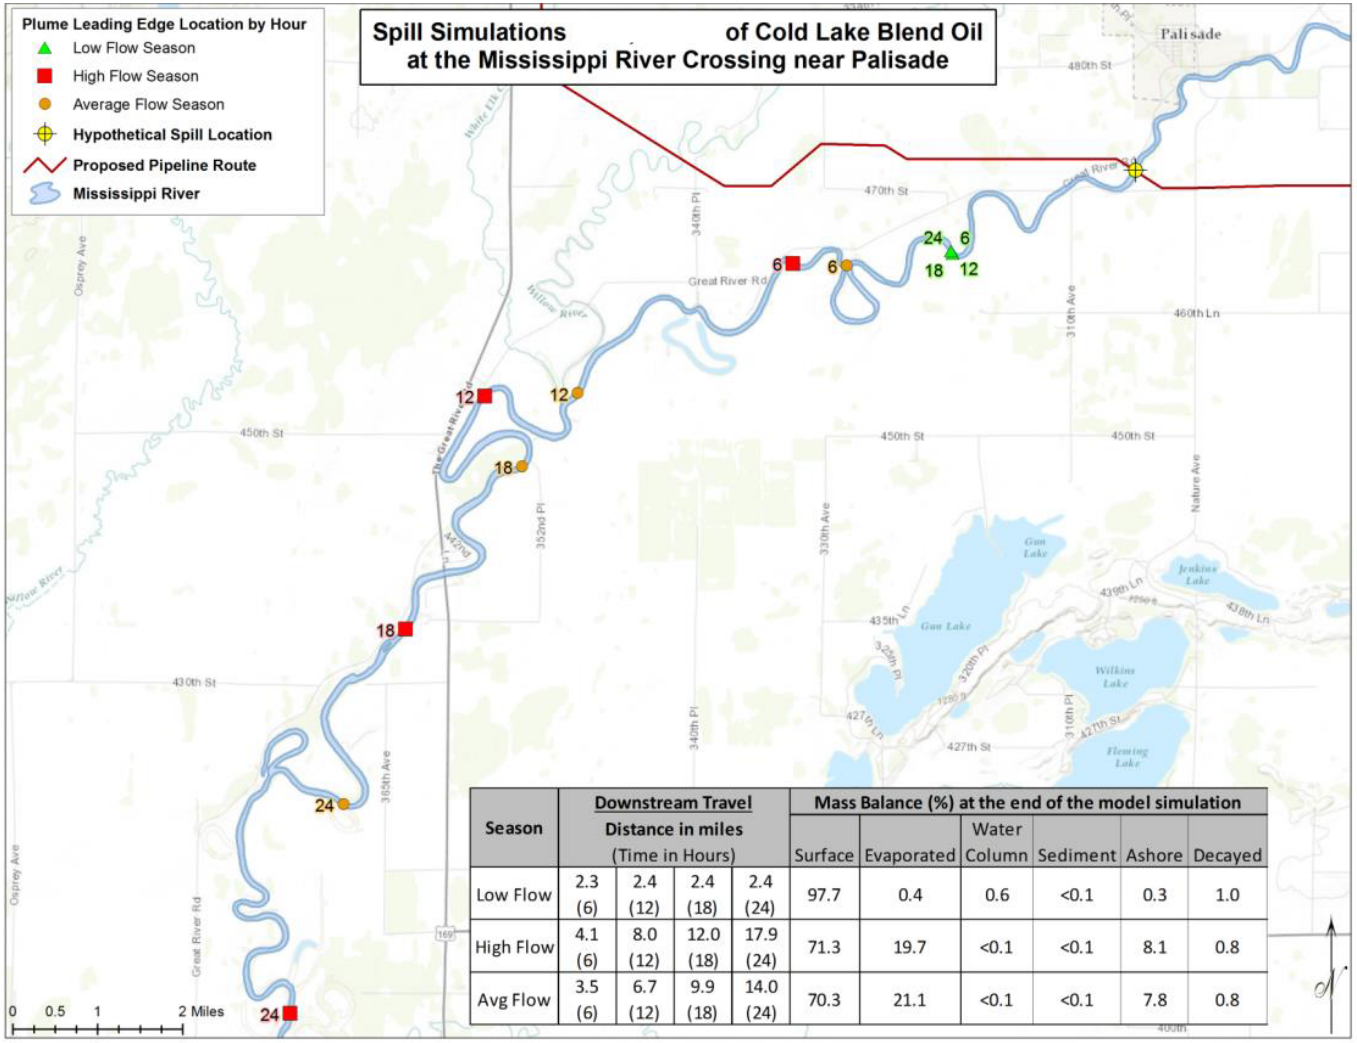
7.7.5 Summary of Predicted Downstream Transport of Bakken and Cold Lake Crude Oils

A summary of the predicted downstream trajectories and mass balance for Cold Lake and Bakken crude oils, under the three seasonal scenarios, is provided in Figure 7-37 and Figure 7-38. These simulations are assumed to provide bounding conditions for a release of heavy or light crude oil types, respectively. The fate of most types of crude oil, if released, would lie within the envelope of predictions for the Cold Lake and Bakken crude oil types. The Cold Lake crude oil was assumed to be CLB for the high flow and average flow scenarios, and to be CLWB for the low flow (winter) scenario. The maximum simulation duration using SIMAP was 24 hours, as it was assumed that emergency response measures to prevent or reduce further downstream transport of released oil would be in place within that length of time.



Symbols on the drawings indicate the river seasonal flow condition (high corresponding to spring freshet, average corresponding to summer-fall conditions, and low corresponding to winter flow under ice). Numbers associated with the symbols indicate the predicted location of the leading edge of the released oil in the river after 6, 12, 18 or 24 hours. Tables inserted within the Figures also provide information on the mass balance (i.e., oil remaining on the surface of the river, evaporated to the atmosphere, dissolved in the water column, deposited to sediment, adhering to river banks, or decaying through photo-oxidation and biodegradation) of the released oil at relevant points in time after the start of the release.

7.7.1.1 Mississippi River at Palisade Release During High Flow (Spring) Period

Under the high flow scenario CLB was predicted to travel downstream in the Mississippi River approximately 4, 8, and 18 miles after 6, 12, and 24 hours, respectively (Figure 7-44). By 24 hours after the hypothetical release, almost all of the released crude oil (71.3%) was predicted to remain on the surface of the Mississippi River, with 19.7% evaporating and 8.1% adhering to shorelines. Less than 1% was predicted to break down through photo-oxidation and biodegradation. Negligible amounts (less than 0.1%) of the heavy oil were predicted to mix in the water column, or deposit to sediment (Figure 7-44).

Bakken crude oil was predicted to follow a similar downstream transport pattern as CLB (Figure 7-45). By 24 hours after the hypothetical release, most (52.2%) of the Bakken crude oil was predicted to have evaporated, with 35.8% remaining on the river surface, approximately 11.4% adhering to shorelines, and less than 1% broken down through photo-oxidation and biodegradation. Negligible amounts (less than 0.1%) of the Bakken crude oil were predicted to mix within the water column or deposit to sediment (Figure 7-45).

Figure 7-45 Predicted Downstream Transport of Bakken Crude Oil at the Mississippi River near Palisade, MN

This pattern of mass balance for both oil types is the result of the oil properties and relatively calm waters (i.e., not a lot of surface breaking disturbances) of the Mississippi River during high and average river flow conditions. Both oil types were predicted to float on the water surface. Owing to the calm water conditions, negligible amounts of either crude oil type were predicted to entrain into the water column. These hypothetical releases were typified by large amounts of floating oil, which are predicted to form thick surface oil slicks downstream from the release. At the end of the 24-hour simulation, floating CLB and Bakken crude oil were predicted to have a thickness greater than 0.04 inches on the water surface, with none of the slick predicted to be less than 0.0004 inches. As a result of the extensive surface oil slicks, oil floating on the river was predicted to evaporate rapidly over the 24-hour simulation. If left unmitigated, both oil types remaining on the river surface after 24 hours could continue to move downstream, with weathering and oiling of shorelines continuing until all of the oil was removed from the water surface.

The potential for entrainment of CLB and Bakken crude oil into the water column was predicted to be low due to the low wind speeds which did not cause surface breaking waves, and the low water velocities, lack of rapids, riffles, and waterfalls in this area of the Mississippi river. Natural weathering resulted in increased viscosity of the CLB, which would further reduce the likelihood of potential entrainment into the water column. Because of this, THCs in the water column were predicted to be extremely low due to the oil remaining on the surface and not entraining within the water column.

Based on SIMAP simulations, most of the dissolved aromatic concentrations associated with the CLB and Bakken crude oil were predicted to be between 1 and 100 ppb. However, brief pulses of concentrations between 2,000 and 5,000 ppb, or greater than 5,000 ppb, were predicted to occur within 24 hours after the release in extremely limited spatial and temporal extents within the Mississippi River for CLB and Bakken crude oil, respectively.

Of the oil that made its way into the water column, a portion could interact with (i.e., become adsorbed to) suspended sediments. For CLB, THCs on the bed sediments were predicted to be generally less than 0.01 g/m^2, with small areas where deposition could be as high as 1 g/m^2. For Bakken crude oil, total hydrocarbon concentrations on the bed sediment were generally predicted to be less than 0.01 g/m^2, with small areas as high as 0.5 g/m^2 (Chapter 6.0).

For the hypothetical CLB release, retention of crude oil along shorelines resulted in predicted values that were generally greater than 500 g/m^2. In contrast, for the Bakken crude oil, shoreline retention values generally ranged from 100 to 500 g/m^2. This difference is due to the greater viscosity and adhesiveness of the CLB crude oil, which results in thicker oiling of shorelines as compared to the Bakken crude oil. Extensive shoreline oiling but limited sediment oiling was predicted for approximately 18 miles of the river, below the release location, under high river flow conditions. The highest sediment concentrations were predicted for the high river flow scenario due to the higher concentration of TSS in the water column. Less oil was expected to reach sediments in the Bakken releases, when compared to the CLB. In the longer term, if not

recovered by emergency response personnel, crude oil that was initially deposited along shorelines could subsequently be deposited to bed sediments, in combination with silt and sand originating from the shoreline contact.

7.7.5.1 Mississippi River at Palisade Release During Average Flow (Summer–Fall) Period

Under the average flow scenario, CLB was predicted to travel downstream in the Mississippi River approximately 4, 7, and 14 miles after 6, 12, and 24 hours, respectively (Figure 7-44). By 24 hours after the hypothetical release, most of the released crude oil (70.3%) was predicted to remain on the surface of the Mississippi River, with 21.1% evaporating, 7.8% adhering to shorelines, and less 1% broken down through photo-oxidation and biodegradation (Figure 7-44). Negligible amounts (less than 0.1%) of the heavy oil were predicted to mix in the water column or deposit to sediment (Figure 7-44).

Bakken crude oil was predicted to follow a similar downstream transport pattern to CLB (Figure 7-45). Most of the Bakken crude oil (55.3%) was predicted to evaporate, with 35.1% remaining on the river's surface, 9% adhering to shorelines, and less than 1% broken down through photo-oxidation and biodegradation. Negligible amounts (less than 0.1%) of the lighter crude oil were predicted to mix within the water column or deposit to sediment (Figure 7-45).

This pattern of mass balance for both oil types is the result of the oil properties and relatively calm waters (i.e., not a lot of surface breaking disturbances) of the Mississippi River during high and average river flow conditions. Both oil types were predicted to float on the water surface. Owing to the calm water conditions, negligible amounts of either crude oil type were predicted to entrain into the water column. These hypothetical releases were typified by large amounts of floating oil, which formed thick surface oil slicks. At the end of the 24-hour simulation, floating CLB and Bakken crude oil were predicted to have a thickness greater than 0.04 inches on the water surface, with none of the slick predicted to be less than 0.0004 inches. As a result of the extensive surface oil slicks, oil floating on the river was predicted to evaporate rapidly over the 24-hour simulation. If left unmitigated, both oil types remaining on the river surface after 24 hours could continue to move downstream, with weathering and oiling of shorelines continuing until all of the oil was removed from the water surface.

The potential for entrainment of CLB and Bakken crude oil into the water column was predicted to be low due to the low wind speeds which did not cause surface breaking waves, and the low water velocities, lack of rapids, riffles, and waterfalls in this area of the Mississippi river. Natural weathering resulted in increased viscosity of the CLB, which would further reduce the likelihood of potential entrainment into the water column. Because of this, total hydrocarbon concentrations in the water column were predicted to be extremely low due to the oil remaining on the surface and not entraining within the water column.

Based on SIMAP simulations, most of the dissolved aromatic concentrations associated with the CLB and Bakken crude oil were predicted to be between 1 and 100 ppb. However, brief pulses of concentrations between 2,000 and 5,000 ppb, or 1,000 and 5,000 ppb, were predicted to

occur within 24 hours after the release in extremely limited spatial and temporal extents within the Mississippi River for CLB and Bakken crude oil, respectively.

Of the oil that made its way into the water column, a portion could interact with suspended sediment. For CLB, total hydrocarbon concentrations on the bed sediment were generally less than 0.01 g/m^2, with small areas as high as 1 g/m^2. For Bakken crude oil, THCs on bed sediment were predicted to be generally less than 0.01 g/m^2, with small areas as high as 0.5 g/m^2.

For the hypothetical CLB release, retention of crude oil along shorelines resulted in predicted values that were generally greater than 500 g/m^2. However, overall the concentrations were predicted to be lower than under high flow conditions. In contrast, for the Bakken crude oil, shoreline retention values generally ranged from 100 to 500 g/m^2. This difference is due to the greater viscosity and adhesiveness of the CLB crude oil, which results in thicker oiling of shorelines as compared to the Bakken crude oil. Extensive shoreline oiling but limited sediment oiling was predicted for approximately 14.5 miles of the river, below the release location, under average river flow conditions. In the longer term, if not recovered by emergency response personnel, crude oil that was initially deposited along shorelines could subsequently be deposited to bed sediments, in combination with silt and sand originating from the shoreline contact.

7.7.1.2 Mississippi River at Palisade Release During Low Flow (Winter) Period

Under the low flow scenario CLWB was predicted to travel downstream in the Mississippi River approximately 2.5 miles within the 24 hour model simulation (Figure 7-44). By 24 hours after the hypothetical release, almost all of the released crude oil (97.7%) was predicted to remain on the surface of the Mississippi River (under ice), with approximately 1% broken down through biodegradation, and less than 1% evaporating, mixing in the water column, or adhering to shorelines (Figure 7-44). Negligible amounts (less than 0.1%) of the heavy oil were predicted to evaporate or deposit to sediment (Figure 7-44).

Under the low flow scenario Bakken crude oil was predicted to travel 0.5 miles downstream in the Mississippi River within the 24 hour model simulation (Figure 7-45). This distance is approximately one-fifth that of the CLWB and is the result of the difference in oil density: Bakken crude oil is less dense than CLWB and would be expected to rise through the water column more rapidly after a release than the CLWB. As a result, lighter oils would spend less time in the water column than heavier oils, travel a lesser distance downstream, and rise to the surface and adhere to the underside of the ice more quickly. By 24 hours after the hypothetical release, almost all of the released crude oil (98.7%) was predicted to remain on the surface of the Mississippi River (under ice), with approximately 1% broken down through biodegradation (Figure 7-45), 0.2% dispersed in the water column, and 0.1% adhering to shoreline. Negligible amounts (less than 0.1%) of the light oil were predicted to evaporate or deposit to sediment (Figure 7-45).

Where CLWB was predicted to adhere to the shoreline, concentrations were generally greater than 500 g/m^2, with some areas less than 1 g/m^2. The soluble portion of the CLWB was predicted to dissolve completely into the water column and be transported downstream. This was a

conservative prediction reflecting the fact that ice cover would strongly limit or prevent the evaporation of volatile hydrocarbons, but also maximizing the potential release of soluble hydrocarbons to the water column.

Based on SIMAP simulations, most of the dissolved aromatic concentrations associated with the CLWB were predicted to be between 1 and 500 ppb. However, brief pulses of concentrations greater than 5,000 ppb were predicted to occur within 24 hours after the release in extremely limited spatial and temporal extents (generally within 1 mile of the release). At the end of the 24-hour simulation, floating oil greater than 0.04 inches thick was predicted to remain on the water surface (beneath the ice), with none of the slick predicted to be less than 0.0004 inches thick.

The soluble portion of the Bakken crude oil was also assumed to dissolve completely into the water column, and was predicted to be transported downstream resulting in elevated dissolved aromatic hydrocarbon concentrations in the water column in some areas. Maximum soluble hydrocarbon concentrations greater than 5,000 ppb were predicted to occur within 24 hours after the release in extremely limited spatial and temporal extents (the first 0.75 miles downstream of the hypothetical release). At the end of the 24-hour simulation, floating oil greater than 0.04 inches thick was predicted to remain on the water surface (beneath the ice), with none of the slick predicted to be less than 0.0004 inches thick.

Where sediment oiling was predicted occur, total hydrocarbon deposition to the bed sediment was generally predicted to be less than 0.01 g/m^2. Patchy oiling of Bakken crude oil was also predicted along shoreline of the Mississippi River near the release site, but most of the oil was predicted to remain trapped under the ice. Slightly lower amounts of Bakken crude oil were predicted along shorelines as compared to CLWB.

7.7.6 Qualitative EHHRA for the Mississippi River near Palisade

In this section the likely environmental effects of a crude oil release at the pipeline crossing location on the Mississippi River are described. A worst case crude oil release from a main-line pipeline, such as described here, would be an unlikely event (Chapter 4.0). The proposed pipeline could carry a variety of crude oil types, ranging from very light (e.g., Bakken crude oil) to heavy (e.g., diluted bitumen such as CLB). Therefore, the following discussion is based on the likely environmental effects of a crude oil release on relevant ecological and human environment receptors (identified in Section 7.7.3), using the predicted geographic extent of effects of released Bakken or CLB crude oil types over the 24 hour simulations as bounding conditions. Effects of season (including temperature, river flow conditions, and receptor presence/absence and sensitivity) were also considered in the analysis. The rationale supporting the effects analysis, based on case studies describing the effects of crude oil releases on the various ecological and human environment receptors, was provided in Section 7.1 and Table 7-78.

7.7.6.1 Terrestrial Receptors

For this modeling scenario, the hypothetical release of crude oil is assumed to enter the Mississippi River with no overland flow. Environmental effects on soils, terrestrial vegetation, and groundwater quality are assumed to be localized, limited in spatial extent, and readily remediated using conventional clean-up techniques. The environmental effects of a crude oil release on land cover receptors are not considered further for this release scenario.

7.7.6.2 Aquatic Receptors

The aquatic environmental and ecological receptors that are most closely associated with the Mississippi River at Palisade scenario are addressed in this section. These receptors include water and sediment quality in rivers, shoreline and riparian habitat, wetlands, aquatic plants, benthic invertebrates, and fish.

Crude oil released into the Mississippi River during the spring (high flow) or summer-fall (average flow) seasons is predicted to travel downstream, interacting with vegetation and seasonal shoreline areas. Based on SIMAP simulations, CLB crude oil and Bakken crude oil were predicted to follow the same downstream transport pattern (each predicted to reach approximately 18 miles downstream 24 hours after a release) and form slicks of similar thickness (generally between 0.0004 and 0.04 inches). However, a greater amount of CLB is predicted to remain on the surface of the Mississippi River after 24 hours as compared to Bakken crude oil (i.e., approximately 70% vs. 36%), while a greater amount of Bakken crude oil is predicted to evaporate as compared to CLB (i.e., approximately 55% vs. 20%). During spring (high flow) and summer-fall (average flow) seasons, both oil types are predicted to have similar amounts adhering to shorelines (i.e., between 8 and 11%), and negligible amounts of either oil type are predicted to mix into the water column or deposit to sediment (i.e., less than 0.1%).

The effects of a crude oil release on benthic invertebrates and fish would depend on the characteristics of the released oil, and environmental conditions at the time of the release. Acute toxicity to fish is commonly but not always observed in association with crude oil releases, and is an indicator that, at least briefly, concentrations of dissolved hydrocarbons (particularly mono-aromatic hydrocarbons, some low molecular weight PAHs, and short-chain aliphatic hydrocarbons) are sufficiently high to cause acute toxicity due to narcosis. The potential for entrainment of CLB and Bakken crude oil into the water column during high and average river flow conditions was predicted to be low due to the low wind speeds, which did not cause surface breaking waves, and the lack of rapids, riffles, and waterfalls in this area of the Mississippi River. Natural weathering resulted in increased viscosity of the CLB, which further reduced the likelihood of potential entrainment into the water column. Because of this, total hydrocarbon concentrations (i.e., whole oil in the water column) were extremely low due to the oil remaining on the surface and not entrained within the water column. Based on SIMAP simulations, most of the dissolved aromatic concentrations associated with the CLB and Bakken crude oil were predicted to be between 1 and 100 ppb. However, brief pulses of concentrations between

1,000 and greater than 5,000 ppb were predicted to occur within 24 hours after the release in extremely limited spatial and temporal extents within the Mississippi River. These areas of high concentration would be expected to move down the river with the flowing water, so that a transient pulse of relatively high exposure to dissolved aromatic hydrocarbon concentrations would be followed by exposure to much lower concentrations.

French McCay (2002) proposed a benchmark lethal concentration (LC50) value of 224 ppb (µg/L) for sensitive aquatic species exposed indefinitely to total aromatic hydrocarbons from crude oil. For species of average sensitivity, a threshold of 1,869 ppb was reported. Given exposure of shorter duration (i.e., less than one day), a considerably higher concentration (perhaps two to three times higher) would be required in order to result in the death of even sensitive species. Therefore, the predicted transient exposure concentrations for dissolved aromatic hydrocarbon compounds in the river water could result in acute lethality to fish that are sensitive or have average sensitivity to hydrocarbons. With these modeled concentrations, lethality could also be expected in isolated areas of the Mississippi within the release trajectory where high concentrations of dissolved aromatic hydrocarbon persist over a period of several days or longer. However, the majority of predicted dissolved aromatic concentrations were much less than 500 ppb.

Of the oil that made its way into the water column, a portion could interact with suspended particulate matter. Where oil is predicted to deposit to sediment, the highest sediment concentrations were predicted for the high river flow scenario due to the higher concentration of TSS in the water column. Slightly less oil was expected to reach sediments in the Bakken releases, when compared to the CLB. The highest sediment concentrations were predicted for the high river flow scenario due to the higher concentration of TSS in the water column. For CLB, total hydrocarbon concentrations in sediment were generally less than 0.01 g/m^2, with small segments as high as 1 g/m^2. For Bakken crude oil, THCs on the sediment were generally less than 0.01 g/m^2, with small segments as high as 0.5 g/m^2.

With limited mixing of crude oil into surface river bed sediments to a depth of less than 0.25 inch, crude oil deposition of less than 0.1 g/m^2 is likely to be undetectable, and without any ecological consequence. Crude oil deposition to sediment of less than 1 g/m^2 would result in sediment hydrocarbon concentrations that would be less than 100 ppm (mg/kg). These low concentrations would also be unlikely to result in significant environmental effects on fish, benthic invertebrates, or other aquatic life. As a result, based on the SIMAP model results, the potential for acute toxicity to fish and benthic invertebrates is expected to be low, and similar for both the Bakken and CLB crude oil types.

The potential for chronic effects of released crude during high and average river flow oil on fish eggs and embryos (i.e., induction of deformities or mortality collectively termed blue sac disease) is expected to be generally low. While the eggs and embryos of these species could be exposed to total PAH concentrations in the river water that could be sufficiently high to induce deformities or cause mortality, these areas of limited and transitory. The potential for blue sac

disease would be greatest for a crude oil release in winter or during the spring freshet, as such crude oil could be dispersed into side-channel and oxbow habitat that is important for spawning fish such as northern pike. While local accumulations could result in adverse effects on developing fish eggs and embryos in the first season following an accidental crude oil release, it is not likely that such effects would persist beyond one year, and effects would occur in only a limited area of the river. Therefore, at the scale of the Mississippi River in Minnesota, it is not likely that such effects would be detectable at a population level.

The potential for phototoxicity caused by an interaction of UV light with PAHs accumulated in fish tissues would be greatest for a crude oil release in summer due to high light intensity and long day length. Small fish that are lightly pigmented or transparent (i.e., embryos, larval and juvenile fish) are most susceptible to phototoxicity. The risk of phototoxicity would be mitigated by high concentrations of suspended sediment and DOC present in the water of the Mississippi River, which would absorb and limit the penetration of UV light into the water column.

The Mississippi River supports emergent, floating and submerged aquatic plants. Where they occur, floating aquatic plants would be expected to be killed if contacted by an oil slick. Submerged aquatic plants would be less vulnerable, as they would be exposed primarily to dissolved hydrocarbons (which is limited in high and average flow conditions), and are not considered likely to be among the most sensitive groups of aquatic biota to such exposure. For a hypothetical release under spring freshet conditions, it is likely that most aquatic plants would still be dormant or submerged, and that environmental effects on this receptor type would be minimal. However, flooded riparian areas and wetland habitats in oxbows would also be exposed to the released oil, and if not properly remediated, crude oil residues could kill plants in these areas. This could affect the biological integrity and productivity of the habitat, and potentially lead to erosion and further damage to the habitat. A release of crude oil in winter would have little direct effect on aquatic plants, as they would be in a dormant state.

During low flow winter conditions, if the release was to occur directly to the river below the ice (as is assumed in the SIMAP model), or if there were openings in the ice that the released oil could penetrate, the oil could travel downstream under the ice, accumulating in the narrow gap between the ice and the river sediment, or accumulating in hollows under the ice as it moved. Results provided in Section 7.7.5.3 provide bounding cases for the products likely to be carried in the pipeline. The SIMAP simulations indicate that heavy crude oil could be carried 5 times farther downstream than light oil (i.e., 2.5 miles vs 0.5 miles from the point of release) under winter low-flow conditions, although this is due to the assumption that the heavy crude oil would only rise slowly through the water column. In reality, with the assumed failure mechanism of a full bore pipeline rupture, it is likely that both types of crude oil would well up from the river bed with a certain amount of momentum, along with entrained river bed muds. Both types of crude oil would probably behave more similarly, near the point of release, than the SIMAP simulation suggests. At the end of the 24-hour simulation, floating oil of both types is predicted to have a thickness between 0.0004 and 0.04 in. at the water surface (beneath the ice). For both oil types, the winter ice would effectively inhibit evaporation. The soluble portion of the CLWB was

predicted to dissolve completely into the water column and be transported downstream. Maximum dissolved aromatic hydrocarbon concentrations greater than 500 ppb were predicted in limited regions within the release extent. However, brief pulses of concentrations greater than 5,000 ppb were predicted to occur 24 hours after the release in extremely limited spatial and temporal extents for CLWB (generally within 1 mile of the release) and Bakken crude oil (generally within 0.75 miles of the release). As noted above, short-term exposure to these concentrations of dissolved aromatic hydrocarbons from crude oil could result in mortality of fish species.

7.7.6.3 Semi-Aquatic Wildlife Receptors

Habitat along the Mississippi River downstream of the hypothetical release location supports amphibians (e.g., frogs, salamander), reptiles (e.g., turtles, snakes), birds (e.g., ducks, geese, shorebirds, raptors), and semi-aquatic mammals (e.g., muskrat, beaver, mink and otter). Details on predicted environmental effects for amphibians and reptiles, birds and mammals are provided below.

7.7.6.3.1 Amphibians and Reptiles

Crude oil released to the Mississippi River during the spring (high flow) or summer-fall (average flow) seasons would be predicted to travel downstream, interacting with vegetation and seasonal shoreline areas. Based on SIMAP simulations, CLB crude oil and Bakken crude oil were predicted to follow the same downstream transport pattern (each predicted to reach approximately 18 miles downstream 24 hours after a release) and form slicks of equal thickness between 0.0004 inches and greater than 0.04 inches. However, a greater amount of CLB is predicted to remain on the surface of the Mississippi River after 24 hours as compared to Bakken crude oil (e.g., approximately 70% vs. 36%), while a greater amount of Bakken crude oil is predicted to evaporate as compared to CLB (e.g., approximately 55% vs. 20%). During spring (high flow) and summer-fall (average flow) seasons, both oil types are predicted to have similar amounts adherence to shorelines (e.g., between 8 and 11%) and negligible amounts (less than 0.1%) of either oil type are predicted to mix within the water column or deposit to sediment.

Within the oil-exposed habitats along the river that support amphibians (adults, juveniles, and eggs), oiling effects including mortality would be observed. Turtles appear to be relatively tolerant of external crude oil exposure, and although these animals are likely to become oiled, mortality of turtles as a result of this exposure is less likely. Reptiles like lizards and snakes are primarily terrestrial species and are less intimately associated with aquatic environments. As a result, exposure of these animals to released crude oils would be limited. After the Kalamazoo River oil spill in 2010, snakes did not appear to be highly exposed to spilled oil. A release of light crude oil during the spring would likely have a greater effect than in summer due to the greater predicted downstream transport distance and interaction with greater areas of riparian and wetland habitats than later in the year.

Amphibians and reptiles undergo a winter dormancy period when temperatures drop below approximately 41 to 45°F. At this time, amphibians and turtles typically bury themselves in river bottom substrates or other similar habitats. Therefore, during the winter (and likely up until April or May when winter ice is gone), these organisms would have very little exposure to released oil moving on the water surface or within the water column.

7.7.6.3.2 Birds

Aquatic and semi-aquatic birds are those that use rivers, lakes, wetlands, and riparian areas as components of their habitat, particularly for nesting and feeding. These birds belong to a variety of guilds including but not limited to waterfowl, divers, gulls and terns, raptors, shorebirds, waders, and some songbirds. They have a variety of dietary preferences, including piscivory, insectivory, omnivory, and herbivory. If exposed to external oiling, the ability of birds to maintain body temperature may be compromised, leading to death as a result of hypothermia. Even if they survive their initial exposure to crude oil, the exposure may require an increase in metabolic rate to survive. In turn this may compromise other life functions such as reproduction or growth. Birds that survive external oiling may experience toxicological stresses as a result of ingesting crude oil residues while preening or attempting to clean and restore the normal properties and functions of feathers. Birds can also transfer potentially lethal quantities of crude oil residue from their feathers to the external surface of eggs, resulting in death of developing embryos.

Unlike many other vertebrate receptors, aquatic bird species in the northern temperate zone are nearly all seasonal migrant species which leave their summer (and often breeding) habitat in the fall for wintering areas farther south where they can find open-water habitat. However, some birds (e.g., Canada goose) will opportunistically remain in freezing conditions if there is reliable open water and a source of food available. Timely capture and rehabilitation of oiled birds may help to mitigate the environmental effects of a crude oil release. During the spring (high flow) season, many migratory birds would be returning to riverine and lacustrine habitats in Minnesota, or migrating through these areas on their way to breeding habitats farther north. With cold water temperatures prevailing, aquatic and semi-aquatic birds contacted by crude oil are likely to die as a result of hypothermia. Waterfowl and other semi-aquatic birds present in the affected river reach would be most affected. Animals upstream, farther downstream, or occupying other nearby habitats, would likely be less affected as it is assumed that emergency response measures to prevent or reduce further possible downstream transport of oil would be in place within 24 hours of the release.

The Mississippi River below Palisade, Minnesota would provide excellent habitat for a variety of waterfowl species, as well as fish-eating raptors, and other species such as kingfisher, herons and shorebirds. The environmental effects of a crude oil release in the summer-fall period are likely to be of similar or lesser magnitude. With rising water temperatures, mortality of lightly oiled adult birds due to hypothermia becomes less likely than in the spring, and the temporary presence of large numbers of migrating individuals is unlikely. However, in the early summer, environmental effects could include egg mortality due to transfer of oil from the feathers of lightly oiled adult birds in the nest, or mortality of young birds due to direct oil exposure or the loss of a parent bird.

Chronic adverse effects on the health of birds that survive their initial exposure to crude oil are also possible as a result of ingesting crude oil residues while preening, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure. Potential effects on aquatic and semi-aquatic birds in the fall would be similar to those in spring, although a smaller overall length of river habitat would be affected due to lower river flows. Mortality of waterfowl and other semi-aquatic bird species would occur, and would likely be similar to effects that were reported following the release of crude oil to the Kalamazoo River in 2010. While the death of these birds would be a serious environmental effect locally, given the length of the Mississippi River in Minnesota, and the abundance of other wetland, lake, river and riparian habitat in the region and state, longer-term population-level effects on semi-aquatic birds are not likely to be observed.

Under winter conditions (March), it was assumed that the Mississippi River would be frozen (100% ice cover). In addition, most waterfowl and other semi-aquatic bird species would migrate south in the winter. Therefore, a crude oil release in winter would be expected to have very limited effects on birds.

7.7.6.3.3 Semi-aquatic Mammals

While the semi-aquatic mammal species found in Minnesota include terrestrial species such as moose and raccoon, this assessment focuses particularly upon species that have a primary association with the aquatic environment such as muskrat and beaver (herbivores), American mink (carnivore-piscivore) and river otter (piscivore). These species are at greater risk of exposure to an oil release in water than more fully terrestrial mammals. The Mississippi River below Palisade, Minnesota, would provide excellent habitat for muskrat and beaver, as well as fish-eating mammals such as American mink and river otter, and incidental omnivorous mammals such as raccoon.

Effects to semi-aquatic mammals are typically described in terms of direct physical effects (e.g., hypothermia due to loss of insulation), direct toxicological effects (e.g., gastro-enteropathy caused by ingestion of crude oil residues while grooming oiled fur or ingesting food), and indirect effects caused by changes to habitat (e.g., land cover and food availability). The spatial extent along the Mississippi River where effects may occur, and the magnitude of effects, is related to the season and river flow rate, and the type of oil released. Effects to semi-aquatic mammals relate more to the amount of time spent in the water and oil-contaminated riparian habitat (and consequent exposure to physical oiling) than to dietary preferences. Timely capture and rehabilitation of oiled mammals may help to mitigate the environmental effects of a crude oil release.

During high and average flow conditions, and based on SIMAP simulations, CLB crude oil and Bakken crude oil were predicted to follow the same downstream transport pattern (each predicted to reach approximately 18 miles downstream 24 hours after a release) and form slicks of equal thickness between 0.0004 in. and greater than 0.04 in. Both oil types are predicted to have similar amounts of adherence to shorelines (e.g., between 8 and 11%) and only very little

amounts of both types of oil are predicted to mix within the water column or deposit to sediment (e.g., less than 0.1%).

During the spring (high flow) season, with cold water temperatures prevailing, semi-aquatic mammals contacted by crude oil are likely to die as a result of hypothermia. Animals upstream, farther downstream where there is no exposure, or occupying other nearby habitats, would likely be unaffected. Therefore, although mortality of a considerable number of semi-aquatic mammals could be expected, large-scale (i.e., regional) population level effects are unlikely. Environmental effects of a crude oil release in the summer-fall period are likely to be of a magnitude similar to or lesser than those associated with a release during spring. With rising water temperatures, mortality of lightly oiled semi-aquatic mammals due to hypothermia is less likely than in the spring. Chronic adverse effects on the health of semi-aquatic mammals that survive their initial exposure to crude oil are possible as a result of ingesting crude oil residues while grooming, or while consuming food items. However, as in the spring, effects are expected to be limited to areas of oil exposure. While the death of these animals would be a serious environmental effect locally, given the length of the Mississippi River in Minnesota, and the abundance of other wetland, lake, river and riparian habitat in the region and state, longer-term population-level effects on semi-aquatic mammals are not likely to be observed.

In the winter months, muskrat and beaver are likely to reduce their activity levels, although American mink and river otter would remain active. Animals that became oiled in the winter would be likely to rapidly die as a result of hypothermia.

7.7.6.4 Human and Socio-Economic Receptors

Crude oils are complex mixtures of hydrocarbon compounds. Light crude oils typically contain more VOCs than heavier crude oils, although diluted bitumen may contain similar amounts of VOCs to light crude oils, depending upon the type and amount of diluent they contain. Air quality in the vicinity of a crude oil release, and along the downstream corridor, would be affected by the release of VOCs (such as benzene, which is often used as an indicator substance) primarily within the first 24 hours of an oil release. For the Mississippi River at Palisade scenario, the community of Palisade, Minnesota (population less than 200 as reported in the census of 2010) is located approximately one mile north of the hypothetical release location. Depending upon the wind direction at the time of a hypothetical crude oil release, receptors in Palisade might or might not be exposed to odor in the first few hours and days. A small number of human receptors would likely also be present in closer proximity to the river, between the hypothetical release location and the downstream extent of the oil trajectory. These individuals would have variable exposure to VOCs and odor, depending upon their location and prevailing wind speed and direction in the event of a crude oil release.

Based on SIMAP simulations, CLB crude oil and Bakken crude oil were predicted to follow similar downstream transport patterns (each predicted to reach approximately 18 miles downstream within 24 hours of a release), and to form slicks of similar thickness during the spring (high flow) or

summer-fall (average flow) seasons. However, a greater amount of Bakken crude oil (greater than 50%) is predicted to evaporate within 24 hours as compared to CLB crude oil (approximately 20%). Therefore, the effects of a release of Bakken crude oil on air quality would be greater than the effects of a release of CLB.

If a crude oil release was to occur in winter, and to be confined below ice on the river, very little of the volatile hydrocarbon present in the oil would be released to the atmosphere as VOCs. Most would be forced to dissolve into the river water, moving downstream, or remain associated with the liquid crude oil at locations where this oil accumulated until spring breakup. At that time, it is likely that the remaining crude oil would be dispersed downstream along the river, although the residual volatile hydrocarbon content and effects on air quality would be lower than the effects described here for a release during the spring freshet.

Typical human health effects associated with short-term (acute) inhalation of volatiles from crude oil include headache, dizziness, nausea, vomiting, cough, respiratory distress, and chest pain. Short-term or repeated skin contact with crude oil may result in dermatitis. The case studies (Section 7.1) do not reveal any instances of human fatality as a result of inhalation of crude oil vapor. Similarly, ATSDR (1995) report that there are no known instances of human fatality as a result of inhalation of vapor from fuel oils, which would be comparable to light crude oils.

The potential for VOC inhalation exposures to the public would be greatest near and downwind from the release site while the released oil is on the water surface. In the unlikely event of a crude oil release, residents in close proximity would become aware of a strong hydrocarbon odor. Most of the volatile hydrocarbons would be lost within the first 24 hours following a release of crude oil. It is also expected that emergency response personnel would contact such residents and advise them to evacuate. Actual or potential exposure to crude oil vapor may result in residents leaving, or being advised to leave their homes for a period of time while the emergency response takes place.

The drinking water intake for Palisade, Minnesota is upstream of the hypothetical release location so effects on water quality for residences in the area are not expected. In addition, no drinking water HCAs were identified along the path of the release. However, in the event of a crude oil release, people would be notified and testing would be completed to confirm the safety of the water supply. Based upon case studies involving crude oil releases elsewhere, this process could take a few days to two weeks, but reports of crude oil releases affecting private wells are rare, making this an unlikely effect.

Relatively little has been published regarding the long-term effects of human exposure to a crude oil release. Health effects observed in residents and clean-up workers in the months following such releases generally do not persist over the long term (Eykelbosh 2014). The International Agency for Research on Cancer (IARC 1989) has determined there is "limited evidence of carcinogenicity" of crude oil in experimental animals and "inadequate evidence of carcinogenicity" of crude oil in humans. Although toxicological effects from short-term exposure

to volatile hydrocarbons are reversible when exposure is reduced, other health effects such as anxiety and depression may occur, and may persist, regardless of whether the individual was physically exposed to hydrocarbons.

No overland transport of released crude oil was modelled for this hypothetical release location. Infiltration of crude oil into soil and subsequently into groundwater is assumed to be negligible.

The Mississippi River downstream from the hypothetical release location crosses through patches of the Waukenabo State Forest and sections of land owned by the BLM. This section of the Mississippi River is also frequented by recreational users for canoeing, fishing and other purposes. Effects on air and water quality, or the presence of crude oil residues in the sediment, riparian or wetland habitat, could potentially disrupt public use of natural resources (e.g., drinking water supplies, hunting, fishing, recreation). Emergency response workers, in cooperation with public health and safety officials, would be active in isolating, containing and recovering released crude oil, as well as notifying the public about the release. Recreational activities would be disrupted following a release of crude oil along the predicted downstream migration route. Fisheries regulators and public health officials typically close fisheries until it is confirmed through monitoring that fish consumption is not a threat to public health. This standard approach is an effective mitigation strategy to protect human receptors for contact with constituents in the oil.

7.7.6.5 Summary and Conclusions

Expected environmental effects to key ecological and human environment receptors after a hypothetical large crude oil release to the Mississippi River near Palisade, Minnesota have been assessed. The proposed pipeline could carry a variety of crude oil types (ranging from very light [e.g., Bakken crude oil] to heavy [e.g., diluted bitumen such as CLB], and the discussion of expected environmental effects on receptors is based on these crude oil types as bounding conditions. Potential terrestrial receptors, aquatic receptors, semi-aquatic wildlife receptors and human and socio-economic receptors were screened to identify those with the most likely interactions with released oil. The results of this assessment are summarized in Table 7-7-6.

Table 7-80 Environmental Effects Summary Table for Pipeline Crude Oil Releases to the Mississippi River at Palisade

Receptor	Expected Environmental Effects of Released Crude Oil to the Mississippi River at Palisade	Relative Effect	
		Light Crude Oil	Diluted Bitumen
Terrestrial Receptors			
Soils	It is assumed in the model that crude oil would enter directly into the Mississippi River with no holdup of oil on land. In the event of an actual oil release, any oil on land would undergo prompt and effective remediation. Residual effects on plant communities, soil or groundwater quality are unlikely.	SAME	SAME
Groundwater		SAME	SAME
Terrestrial Vegetation		SAME	SAME
Aquatic Receptors			
Rivers (Mississippi River)	Both light and heavy oil would travel downstream from the release location, affecting the Mississippi River. Lighter crude oils and heavier crude oils are predicted to follow the same downstream transport pattern (each predicted to reach approximately 18 miles downstream within 24 hours after a release), and form slicks of similar thickness (between 0.0004 inches and greater than 0.04 inches). During spring (high flow) and summer-fall (average flow) seasons, a greater amount of CLB is predicted to remain on the surface of the Mississippi River after 24 hours as compared to Bakken crude oil (e.g., approximately 70% vs. 36%). However, both oil types are predicted to have similar amounts adherence to shorelines (e.g., approximately 8% for the CLB and 9-11% for the Bakken). Negligible amounts of either crude oil type are predicted to mix within the water column or deposit to sediment. In winter, simulations indicate that heavy crude oil could be carried farther downstream than lighter oil (i.e., 2.5 miles vs. 0.5 miles from the point of release), but this may be due to assumptions in the model. Overall, the SIMAP simulations indicate similar effects of both crude oil types on the aquatic habitat of the Mississippi River at Palisade, Minnesota.	SAME	SAME
Sediment	In all three seasons, both oil types are predicted to have very little mixing within the water column or deposition to sediment (e.g., less than 0.1%). Neither the light nor the heavy oil type is likely to reach a density greater than that of the water and sink directly to the sediment within the first few days following release. Where deposition is predicted, a slightly higher concentration of CLB is predicted in sediment than for Bakken crude oil. However, neither is predicted to be deposited to sediments at concentrations that would seriously affect aquatic life.	SAME	SAME
